Meaning of acronyms:
DB: Dry bulb temperature, °C *WB: Wet bulb temperature, °C*
MCWB: Mean coincident wet bulb temperature, °C
Lat: Latitude, ° *Long: Longitude, °* *Elev: Elevation, m*
DP: Dew point temperature, °C *HR: Humidity ratio, g of moisture per kg of dry air* *WS: Wind speed, m/s*
MCDB: Mean coincident dry bulb temperature, °C *HDD and CDD 18.3: Annual heating and cooling degree-days, base 18.3°C, °C-day*

Meaning of acronyms:
DB: Dry bulb temperature, °C *WB: Wet bulb temperature, °C*
MCWB: Mean coincident wet bulb temperature, °C
Lat: Latitude, ° *Long: Longitude, °* *Elev: Elevation, m*
DP: Dew point temperature, °C *HR: Humidity ratio, g of moisture per kg of dry air* *WS: Wind speed, m/s*
MCDB: Mean coincident dry bulb temperature, °C *HDD and CDD 18.3: Annual heating and cooling degree-days, base 18.3°C, °C-day*

Station	Lat	Long	Elev	Heating DB		Cooling DB/MCWB						Evaporation WB/MCDB				Dehumidification DP/HR/MCDB						Extreme Annual WS			Heat./Cool. Degree-Days

Meaning of acronyms:
DB: Dry bulb temperature, °C *WB: Wet bulb temperature, °C*
MCWB: Mean coincident wet bulb temperature, °C
Lat: Latitude, ° *Long: Longitude, °* *Elev: Elevation, m*
DP: Dew point temperature, °C *HR: Humidity ratio, g of moisture per kg of dry air* *WS: Wind speed, m/s*
MCDB: Mean coincident dry bulb temperature, °C *HDD and CDD 18.3: Annual heating and cooling degree-days, base 18.3°C, °C-day*

Station	Lat	Long	Elev	Heating DB		Cooling DB/MCWB						Evaporation WB/MCDB				Dehumidification DP/HR/MCDB						Extreme Annual WS			Heat./Cool. Degree-Days	
						0.4%		1%		2%		0.4%		1%		0.4%			1%							
				99.6%	99%	DB / MCWB		DB / MCWB		DB / MCWB		WB / MCDB		WB / MCDB		DP / HR / MCDB			DP / HR / MCDB			1%	2.5%	5%	HDD / CDD 18.3

Meaning of acronyms:
DB: Dry bulb temperature, °C *WB: Wet bulb temperature, °C*
MCWB: Mean coincident wet bulb temperature, °C
Lat: Latitude, ° *Long: Longitude, °* *Elev: Elevation, m*
DP: Dew point temperature, °C *HR: Humidity ratio, g of moisture per kg of dry air* *WS: Wind speed, m/s*
MCDB: Mean coincident dry bulb temperature, °C *HDD and CDD 18.3: Annual heating and cooling degree-days, base 18.3°C, °C-day*

Meaning of acronyms:
DB: Dry bulb temperature, °C *WB: Wet bulb temperature, °C*
MCWB: Mean coincident wet bulb temperature, °C
Lat: Latitude, ° *Long: Longitude, °* *Elev: Elevation, m*
DP: Dew point temperature, °C *HR: Humidity ratio, g of moisture per kg of dry air* *WS: Wind speed, m/s*
MCDB: Mean coincident dry bulb temperature, °C *HDD and CDD 18.3: Annual heating and cooling degree-days, base 18.3°C, °C-day*

Station	Lat	Long	Elev	Heating DB		Cooling DB/MCWB						Evaporation WB/MCDB				Dehumidification DP/HR/MCDB						Extreme Annual WS			Heat./Cool. Degree-Days

Meaning of acronyms:
DB: Dry bulb temperature, °C *WB: Wet bulb temperature, °C*
MCWB: Mean coincident wet bulb temperature, °C
Lat: Latitude, ° *Long: Longitude, °* *Elev: Elevation, m*
DP: Dew point temperature, °C *HR: Humidity ratio, g of moisture per kg of dry air* *WS: Wind speed, m/s*
MCDB: Mean coincident dry bulb temperature, °C *HDD and CDD 18.3: Annual heating and cooling degree-days, base 18.3°C, °C-day*

Station	Lat	Long	Elev	Heating DB		Cooling DB/MCWB						Evaporation WB/MCDB				Dehumidification DP/HR/MCDB						Extreme Annual WS			Heat./Cool. Degree-Days

Meaning of acronyms:
DB: Dry bulb temperature, °C *WB: Wet bulb temperature, °C*
MCWB: Mean coincident wet bulb temperature, °C
Lat: Latitude, ° *Long: Longitude, °* *Elev: Elevation, m*
DP: Dew point temperature, °C *HR: Humidity ratio, g of moisture per kg of dry air* *WS: Wind speed, m/s*
MCDB: Mean coincident dry bulb temperature, °C *HDD and CDD 18.3: Annual heating and cooling degree-days, base 18.3°C, °C-day*

Station	Lat	Long	Elev	Heating DB		Cooling DB/MCWB						Evaporation WB/MCDB				Dehumidification DP/HR/MCDB						Extreme Annual WS			Heat./Cool. Degree-Days

Meaning of acronyms:
DB: Dry bulb temperature, °C *WB: Wet bulb temperature, °C*
MCWB: Mean coincident wet bulb temperature, °C
Lat: Latitude, ° *Long: Longitude, °* *Elev: Elevation, m*
DP: Dew point temperature, °C *HR: Humidity ratio, g of moisture per kg of dry air* *WS: Wind speed, m/s*
MCDB: Mean coincident dry bulb temperature, °C *HDD and CDD 18.3: Annual heating and cooling degree-days, base 18.3°C, °C-day*

Station	Lat	Long	Elev	Heating DB		Cooling DB/MCWB						Evaporation WB/MCDB				Dehumidification DP/HR/MCDB						Extreme Annual WS			Heat./Cool. Degree-Days	
						0.4%		1%		2%		0.4%		1%		0.4%			1%

Meaning of acronyms:
DB: Dry bulb temperature, °C *WB: Wet bulb temperature, °C*
MCWB: Mean coincident wet bulb temperature, °C
Lat: Latitude, ° *Long: Longitude, °* *Elev: Elevation, m*
DP: Dew point temperature, °C *HR: Humidity ratio, g of moisture per kg of dry air* *WS: Wind speed, m/s*
MCDB: Mean coincident dry bulb temperature, °C *HDD and CDD 18.3: Annual heating and cooling degree-days, base 18.3°C, °C-day*

Meaning of acronyms:
DB: Dry bulb temperature, °C *WB: Wet bulb temperature, °C*
MCWB: Mean coincident wet bulb temperature, °C
Lat: Latitude, ° *Long: Longitude, °* *Elev: Elevation, m*
DP: Dew point temperature, °C *HR: Humidity ratio, g of moisture per kg of dry air* *WS: Wind speed, m/s*
MCDB: Mean coincident dry bulb temperature, °C *HDD and CDD 18.3: Annual heating and cooling degree-days, base 18.3°C, °C-day*

Station	Lat	Long	Elev	Heating DB		Cooling DB/MCWB						Evaporation WB/MCDB				Dehumidification DP/HR/MCDB						Extreme Annual WS			Heat./Cool. Degree-Days

Meaning of acronyms:
DB: Dry bulb temperature, °C *WB: Wet bulb temperature, °C*
MCWB: Mean coincident wet bulb temperature, °C
Lat: Latitude, ° *Long: Longitude, °* *Elev: Elevation, m*
DP: Dew point temperature, °C *HR: Humidity ratio, g of moisture per kg of dry air* *WS: Wind speed, m/s*
MCDB: Mean coincident dry bulb temperature, °C *HDD and CDD 18.3: Annual heating and cooling degree-days, base 18.3°C, °C-day*

Station	Lat	Long	Elev	Heating DB		Cooling DB/MCWB						Evaporation WB/MCDB				Dehumidification DP/HR/MCDB						Extreme Annual WS			Heat./Cool. Degree-Days

Meaning of acronyms:
DB: Dry bulb temperature, °C *WB: Wet bulb temperature, °C*
MCWB: Mean coincident wet bulb temperature, °C
Lat: Latitude, ° *Long: Longitude, °* *Elev: Elevation, m*
DP: Dew point temperature, °C *HR: Humidity ratio, g of moisture per kg of dry air* *WS: Wind speed, m/s*
MCDB: Mean coincident dry bulb temperature, °C *HDD and CDD 18.3: Annual heating and cooling degree-days, base 18.3°C, °C-day*

Station	Lat	Long	Elev	Heating DB		Cooling DB/MCWB						Evaporation WB/MCDB				Dehumidification DP/HR/MCDB						Extreme Annual WS			Heat./Cool. Degree-Days

FENESTRATION is an architectural term that refers to the arrangement, proportion, and design of window, skylight, and door systems in a building. Fenestration can serve as a physical and/or visual connection to the outdoors, as well as a means to admit solar radiation for daylighting and heat gain to a space. Fenestration can be fixed or operable, and operable units can allow natural ventilation to a space and egress in low-rise buildings.

Fenestration affects building energy use through four basic mechanisms: thermal heat transfer, solar heat gain, air leakage/ventilation/exchange, and daylighting. Fenestration can be used to positively influence a building's energy performance by (1) using glazing and framing to minimize conductive heat loss, (2) using glazing and shading strategies to control solar heat gain to supplement heating and minimize cooling requirements, (3) specifying low-air-leakage fenestration products, (4) integrating fenestration into natural ventilation strategies that can reduce energy use for cooling and outdoor air requirements, and (5) using daylight to offset lighting requirements.

Today's designers and builders; minimum energy standards and codes; green building standards, codes, and rating programs; and energy efficiency incentive programs are seeking more from fenestration systems and giving credit for high-performing products. Window, skylight, and door manufacturers are responding with new and improved products to meet these demands. With the widespread use of simulation software, designing to improve thermal performance of fenestration products has become much easier. Through participation in rating and certification programs that require the use of this software, fenestration manufacturers can take credit for these improvements through certified ratings.

A designer should consider architectural and code requirements, thermal performance, daylight performance, air leakage, energy and environmental impacts, economic criteria, and human comfort when selecting fenestration. Typically, a wide range of fenestration products is available that meet the specifications for a project. Refining the specifications to improve energy performance and enhance a living or work space can result in lower energy costs, increased productivity, and improved thermal and visual comfort.

The preparation of this chapter is assigned to TC 4.5, Fenestration.

1. FENESTRATION COMPONENTS

Fenestration components include glazing material, either glass or plastic; framing, insulation, mullions, muntin bars, dividers, and opaque door slabs; and indoor and outdoor shading devices such as louvered blinds, drapes, roller shades, lightshelves, metal grills, and awnings. In this chapter, **fenestration** and **fenestration systems** refer to the basic assemblies and components of window, skylight, and door systems that are part of the building envelope.

1.1 GLAZING UNITS

Most fenestration currently manufactured using glass contains a glazing system that is packaged in the form of a **glazing unit**. A glazing unit consists of two or more glazing layers that are held apart by an edge seal. Figure 1 shows the construction of a typical double-glazing unit.

The most common glazing material is glass, although polymer (plastic) is sometimes used, either in the form of intermediate films bonded to glass, or as stand-alone glazing material popular in some skylight products. Both may be clear, tinted, coated, laminated,

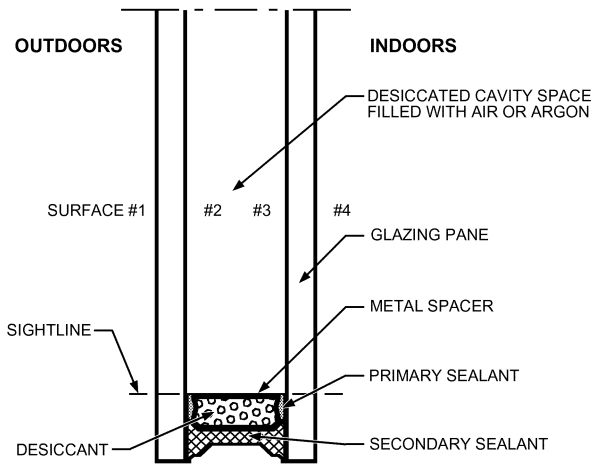

Fig. 1 Construction Details of Typical Double-Glazing Unit

tempered, patterned, or obscured, and polymer types can be easily shaped, textured, and profiled using several processing options. Clear glazing material transmits more than 75% of the incident solar radiation and more than 85% of the visible light. Body-tinted glass containing a pigment is available in many colors, all of which differ in the amount of solar radiation and visible light they transmit and absorb. Some coated glazing materials are highly reflective (e.g., mirrors), whereas others have very low reflectance. Some **spectrally selective glazing** products include coatings that have a visible light transmittance more than double their solar transmittance; these are desirable for good daylighting while minimizing cooling loads. Coatings that reduce radiant heat exchange are called **low-emissivity (low-e) coatings**. Laminated glass is made of two panes of glass adhered together. The interlayer between the two panes of glass is typically plastic and may be clear, tinted, or coated. Tempered glass is designed for safety and shatters into pebble-sized pieces when broken. Patterned glass is a durable ceramic frit applied to a glass surface in a decorative pattern. Obscured glass is translucent and is typically used in privacy applications.

Low-e coated glass is energy efficient, improves daylighting potential, and enhances occupant comfort. Thus, it is now used in the vast majority of fenestration products. Low-e coatings are typically applied to one of the protected internal surfaces of the glazing unit (surface #2 or #3 in Figure 1), but some manufacturers now offer double- or triple-glazed products with an additional low-e coating on the exposed room-side surface (surface #4 in Figure 1, or what would be #6 in triple glazing). Low-e coatings can also be applied to thin plastic films for use either as one of the middle layers in glazing units with three or more layers (stretched and held in place by a spacer system), or surface-applied film, where the exposed low-e coating is protected by a very thin, thermal-IR (TIR) transparent protective layer.

A wide variety of low-e coatings are used today. Physically, they can be divided into either soft- or hard-coat types. **Soft-coat low-e** is fabricated using a sputtering process in a vacuum chamber. This is done as a post-processing phase after glass has been produced, cut, and stored. The resulting coating is very fragile, especially to the effects of moisture, so these coatings are normally protected inside the sealed glazing unit. **Hard coatings** are created using chemical vapor deposition and are applied to the glass while it is still being floated in its final phases of production. This creates a durable low-e coating that can be exposed to moisture and elements.

From a performance standpoint, categories include (1) high versus low solar gain, (2) spectrally selective, (3) reflective, (4) absorptive, and (5) high light-to-solar-gain (LSG) ratio. Some of these categories are related and causal. As a rule of thumb, soft coats are often low solar gain, whereas hard coats are usually high solar gain.

High-solar-gain coatings, which are more transparent to the whole solar spectrum, are used primarily on south facades in northern heating climates in the northern hemisphere (and, conversely, on north facades in southern heating climates in the southern hemisphere), so solar heat gain during the day can offset thermal heat loss during long, cold winter nights. When this coating is applied to indoor-facing glazing lites (although still facing the glazing cavity), it further increases the solar heat gain coefficient (SHGC), because a higher portion of absorbed solar radiation is transferred to the room (inward-flowing fraction). Their low emissivity helps reduce thermal IR radiation, resulting in increased thermal insulation.

Low-solar-gain coatings, which are usually spectrally selective [blocking admission of the near infrared portion of the solar spectrum, also known as near IR (NIR) or solar IR], are typically applied in hot, cooling-dominated regions to reduce solar heat gains, or in buildings where solar heat gains are not desirable (e.g., commercial buildings with large fenestration areas or high internal heat gains). Such coatings are normally applied to the outdoor-facing glazing lite to reduce the inward-flowing fraction of SHGC. The glass surface's low emissivity also reduces thermal IR radiation heat transfer and therefore increases thermal resistance of the fenestration product. Although the majority of low-e coatings are applied to the glazing surface facing the glazing cavity, increasing numbers of durable coatings are being applied to the room-facing glazing surface. This further improves thermal performance (U-factor) by substantially reducing thermal IR radiation heat transfer on the room side of the window. However, in building spaces with higher indoor humidity levels in cold climates, this approach may significantly increase the risk of moisture condensation on glass surfaces. A new class of low-e surface-applied films may be applied as a retrofit measure to the indoor-facing glass surface; these films can perform similarly to low-e coated glass, so their use is more likely to be as an easy retrofit measure, removing the need to replace glass or sash.

In addition to low-e, **fill gases** such as argon, krypton, and xenon are used in lieu of air in the gap between glass panes. These fill gases reduce convective heat transfer across the glazing cavity. Krypton and xenon also reduce gap width, because their optimal gap widths are nearly half that of air.

The main requirements of the edge seal are to exclude moisture, provide a desiccant for the sealed space, and retain the glazing unit's structural integrity. Further, the edge seal isolates the cavity between the glazing materials, thereby reducing the number of surfaces to be cleaned, and creating an enclosure suitable for nondurable low-e coatings and/or fill gases. The edge seal is composed of a spacer, single- or multilevel sealant, and desiccant.

The **spacer** separates glazing layers and provides a surface for primary and secondary sealant adhesion. Several types of spacers are used, each of which provides different heat transfer properties, depending on spacer material and geometry.

Heat transfer at the edge of the glazing unit is greater than at its center because of (1) heat flow through the spacer system and (2) convective flow, which creates an area of higher convective heat transfer as the gas turns from one glazing to the other. To minimize this heat flow, warm-edge spacers have been developed that reduce edge heat transfer by using materials (e.g., stainless steel, galvanized steel, tin-plated steel, polymers, foamed silicone) of lower thermal conductivity than the typical aluminum alloy from which spacers have often been made. Fusing or bending the corners of the spacer minimizes moisture and hydrocarbon vapor transmission from the gap space.

Several different sealant configurations are used in glazing unit construction. In **dual-seal construction**, a primary seal minimizes moisture transmission and gas escape. A secondary seal provides structural integrity between the lites of the glazing unit, and ensures long-term adhesion and greater resistance to solvents, oils, and short-term water immersion. In typical dual-seal construction, the primary seal is made of compressed polyisobutylene (PIB), and the secondary seal is made of silicone, polysulfide, or polyurethane. **Single-seal construction** depends on a single sealant to adhere the glazing to the spacer and to minimize moisture transmission and gas escape. Single-seal construction is generally more cost effective than dual-seal systems. **Dual-seal-equivalent (DSE)** materials take advantage of advanced cross-linking polymers that provide low moisture transmission and structural properties equivalent to dual-seal systems.

Desiccants are used to absorb moisture trapped in the glazing unit during assembly or that gradually diffuses through seals after construction. Typical desiccants include molecular sieve, silica gel, or a matrix of both materials.

1.2 FRAMING

The three main categories of fenestration framing materials are wood, metal, and polymers. Wood has good structural integrity and insulating value but low resistance to weather, moisture, warpage, and organic degradation (from mold and insects). Metal is durable and has excellent structural characteristics, but it has very poor

Licensed for single user. © 2021 ASHRAE, Inc.

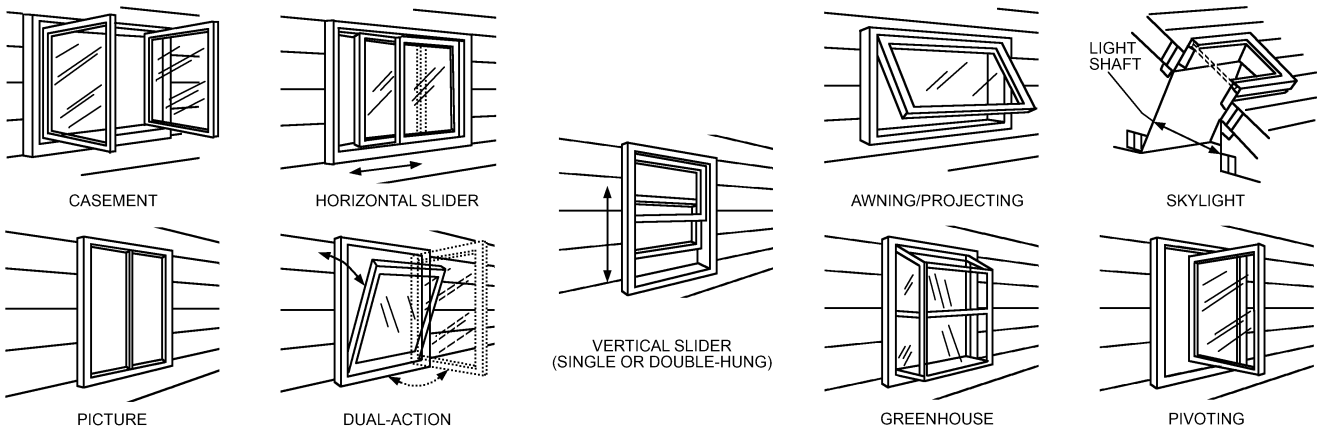

Fig. 2 Various Framing Configurations for Residential Fenestration

thermal performance. The metal of choice in fenestration is almost exclusively aluminum alloy, because of its ease of manufacture, low cost, and low mass, but aluminum alloy has a thermal conductivity roughly 1000 times that of wood or polymers. Steel is sometimes used. Although lower in its thermal conductivity, the overall U-factor of a steel frame is similar to that of an aluminum frame of the same geometry. The poor thermal performance of metal-frame fenestration can be improved with a thermal break (a nonmetal component that separates the metal frame exposed to the outdoors from the surfaces exposed to the indoors). However, to be most effective, there must be thermal breaks in all operable sashes as well as in the frame. Polymer frames are made of extruded vinyl [unplasticized PVC (uPVC)] or pultruded fiberglass (glass-reinforced polyester). Their thermal and structural performance is similar to that of wood. Vinyl frames for large fenestration must be reinforced, which degrades their thermal performance slightly and substantially increases their weight. Polymer frames are generally hollow and thus can also be filled with polyurethane insulation, which reduces convective and radiative heat transfer, thereby achieving a better thermal performance than wood.

Manufacturers sometimes combine these materials as clad units (e.g., vinyl-clad aluminum, aluminum-clad wood, vinyl-clad wood) to increase durability, improve thermal performance, or improve aesthetics. In addition, curtain wall systems for commercial buildings may be structurally glazed, and the outdoor "framing" is simply rubber gaskets or silicone.

Generally, the framing system categorizes residential fenestration, as shown by the examples of traditional basic types in Figure 2. The glazing system can be mounted either directly in the frame (a direct-glazed or direct-set fenestration, which is not operable) or in a sash that moves in the frame (for an operating fenestration). In operable fenestration, a weather-sealing system between the frame and sash reduces air and water leakage.

1.3 SHADING

Shading devices are available in a wide range of products that differ greatly in their appearance and energy performance. They include louvered shades (e.g., venetian blinds, vertical blinds, louvered shutters), roller shades, solar screens, cellular shades, awnings, roller shutters, draperies (curtains), roman shades, perforated panels, etc. Shades can be positioned as indoor, outdoor, or between-glazing products. When shades are applied after the fenestration unit was installed, a popular retrofit measure, these products are called **fenestration attachments**. When a fenestration unit is sold with matched shading as a complete assembly, the shade is called **integral**. Materials used include metal, wood, polymer, woven, and nonwoven fabrics.

The ability of shading devices to control solar gains depends mainly on the location of the device. Shades on the outdoor side of the glazing can effectively reduce solar heat gains, but need more frequent maintenance and are often difficult to adjust. Conversely, indoor devices are ubiquitous and easier to maintain and operate, but may not be as effective in providing significant solar heat gain control, depending on the glazing type, shade properties, and control (Barnaby et al. 2009; Lee and Selkowitz 1995; Moeseke et al. 2007; Shen and Tzempelikos 2012; Tzempelikos and Athienitis 2007; Wright et al. 2009a). Shading devices often do not produce any significant improvement in a fenestration system's U-factor (Barnaby et al. 2009; Wright et al. 2009b). However, several classes of insulating shades (e.g., roller shutters, cellular shades, window quilts) can provide substantial insulating value and be used as an effective retrofit option to improve thermal resistance, especially if they are sealed tightly around the perimeter, and are not porous to air.

Shading devices are well suited to deal with daylighting, privacy, views, glare, and thermal comfort issues. Some products, such as properly adjusted venetian blinds, are quite versatile in this respect. Motorized shading devices can be adjusted under changing outdoor conditions to reduce glare, maximize daylight, reduce internal temperatures (Newsham 1994; Reinhart 2004), or improve thermal comfort to building occupants (Bessoudo et al. 2010) while also providing increased hours of view to the outdoor (Rao and Tzempelikos 2012).

Shading of vertical fenestration is not confined to the use of shading devices. Building elements such as window reveals, side fins, and overhangs can also offer effective shading. Metal grilles with fixed louvers mounted horizontally at the top of a fenestration can block solar gain while still letting some light through, thereby avoiding the negative impacts of solid structural overhangs that act as thermal bridges in the building envelope and reduce daylight. Light shelves can provide shading and also redirect sunlight deeper into the room to provide a more even spatial distribution of daylight in a space. Metal perforated panels are a suitable compromise between completely cutting out views and alleviating glare and overillumination issues. Outdoor vegetative shading is particularly effective in reducing solar heat gain while enhancing the outdoor scene, but may be hard to maintain and also not be persistent over multiple years.

2. DETERMINING FENESTRATION ENERGY FLOW

Energy flows through fenestration via (1) conductive and convective heat transfer caused by the temperature difference between

Licensed for single user. © 2021 ASHRAE, Inc.

outdoor and indoor air; (2) net long-wave (above 2500 nm) radiative exchange between the fenestration and its surroundings and between glazing layers; (3) short-wave (below 2500 nm) solar radiation incident on the fenestration product, either directly from the sun or reflected from the ground or adjacent objects; and (4) air leakage through the fenestration. Simplified calculations are based on the observation that temperatures of the sky, ground, and surrounding objects (and hence their radiant emission) correlate with the outdoor air temperature. This is not the case for clear skies, particularly at night, which can be much colder than ambient air. The radiative interchanges are then approximated by assuming that all the radiating surfaces (including the sky) are at the same temperature as the outdoor air. With this assumption, the basic equation for the steady-state energy flow Q through a fenestration is

$$Q = UA_{pf}(t_{out} - t_{in}) + (\text{SHGC})A_{pf}E_t + (\text{AL})A_{pf}\rho C_p(t_{out} - t_{in}) \quad (1)$$

where

Q = instantaneous energy flow, W
U = overall coefficient of heat transfer (U-factor), W/(m²·K)
A_{pf} = total projected area of fenestration (product's rough opening in wall or roof less installation clearances), m²
t_{in} = indoor air temperature, °C
t_{out} = outdoor air temperature, °C
SHGC = solar heat gain coefficient, dimensionless; also known as *g*-value in Europe
E_t = incident total irradiance, W/m²
AL = air leakage at current conditions, m³/(s·m²)
ρ = air density, kg/m³
C_p = specific heat of air, kJ/kg·K

Here, the first term on the right-hand side of Equation (1) represents heat transfer resulting from a temperature difference across the fenestration, the second term represents heat transfer caused by solar radiation, and the last term represents heat transfer caused by air leakage. The sections on U-factor (Thermal Transmittance), Solar Heat Gain Coefficient and Visible Transmittance, and Air Leakage discuss these topics, respectively.

The main justification for Equation (1) is its simplicity, achieved by collecting all the linked radiative, conductive, and convective energy transfer processes into U and SHGC. Note, however, that the values of U and SHGC vary because (1) convective heat transfer rates vary as fractional powers of temperature differences or free-stream speeds, (2) variations in temperature caused by weather or climate are small on the absolute temperature scale (K) that controls radiative heat transfer rates, (3) fenestration systems always involve at least two thermal resistances in series, and (4) solar heat gain coefficients depend on solar incident angle and spectral distribution. Using U and SHGC values taken from product ratings causes some error in calculating Q. Of the two, the larger error results from the use of normal-incidence SHGC.

3. U-FACTOR (THERMAL TRANSMITTANCE)

In the absence of sunlight, air infiltration, and moisture condensation, the first term on the right side of Equation (1) represents the heat transfer rate through a fenestration system. Most fenestration systems consist of transparent multipane glazing units and opaque elements comprising the sash and frame (hereafter called **frame**). The glazing unit's heat transfer paths are subdivided into center-of-glass, edge-of-glass, and frame contributions (denoted by subscripts *cg*, *eg*, and *f*, respectively). Consequently, the total rate of heat transfer through a fenestration system can be calculated knowing the separate contributions of these three paths. (When present, glazing dividers, such as decorative grilles and muntin bars, also affect heat transfer, and their contribution must be considered.) The overall U-factor is estimated using area-weighted U-factors for each contribution by

$$U = \frac{U_{cg}A_{cg} + U_{eg}A_{eg} + U_fA_f}{A_{pf}} \quad (2a)$$

Note that a product frame normally consists of several different areas, and that, for example, U_fA_f is really $\sum U_{fi}A_{fi}$, where i represents each frame region (e.g., sill, jamb, head, meeting rail). Likewise, each "edge of glazing" region is adjacent to a different frame region, so $U_{eg}A_{eg}$ is really $\sum U_{egi}A_{egi}$. Equation (2a) is used in North America [e.g., for fenestration ratings by the National Fenestration Rating Council (NFRC)], Australia [by the Australian Fenestration Rating Council (AFRC; www.afrc.org.au)], India, and other countries. This approach is described as one of the two options in ISO *Standard* 15099:2003 and is the basis of the calculation used by the Lawrence Berkeley National Lab WINDOW program (LBNL 2016), a widely used software tool for modeling fenestration products' solar-optical and thermal performance. ASHRAE-derived environmental conditions, as used by the NFRC, are applied when Equation (2a) is used. These environmental conditions are detailed in Table 2.

When a fenestration product has glazed surfaces in only one direction, the sum of the areas equals the projected area A_{pf}. Skylights, greenhouse/garden windows, bay/bow windows, etc., because they extend beyond the plane of the wall/roof, have greater surface area for heat loss than fenestration with a similar glazing option and frame material; consequently, U-factors for such products are greater than for the nonprojecting versions. When the slope of a multiglazed fenestration product varies from vertical, the gas in the glazing cavity begins to exhibit vortices that also increase heat flow per unit area. This results in a further U-Factor penalty for products rated at a slope (such as skylights).

In Europe and in some other parts of the world, U-factor is calculated differently: instead of the area-based, edge-of-glass term of Equation (2a), a linear thermal transmittance term Ψ_g is used to describe heat transfer near the perimeter of the glass area. This length-weighted method follows an alternative standard, ISO *Standard* 10077-2:2012, and is also described as second option in ISO *Standard* 15099.

$$U = (U_{cg}A_{cg} + \Psi_g l_g + U_fA_f)/A_{pf} \quad (2b)$$

where l_g is the perimeter length of the entire vision area, delimited by the sightline. ISO *Standards* 10077-2 and 10077-1:2006 use simpler algorithms than ISO *Standard* 15099. In many fenestration systems, this leads to a different apparent U-factor, depending on which standard was followed. In a globalized economy, it is essential that designers and specifiers are aware of this lack of harmonization and that straight conversion between these standards is not possible.

Comparison Between Area-Weighted and Length-Weighted Methods

Glazing units (double- and triple-pane, many with low-e coatings and noble gas fills) were modeled for U-factor and reviewed by Curcija (2005) and van Dijk (2003). The studies showed that ISO 10077 versus NFRC differences in glazing U-factor can be as great as 0.3 W/(m²·K). These discrepancies are larger than the precision with which U-factors are reported for ratings under the European and NFRC systems. Therefore, for some glazing systems a noticeable difference in U-factor will be seen.

In addition to differences between center-of-glass U-factors obtained by the two methods, it is important to note that large differences can occur in frame U-factors; ISO *Standard* 15099/NFRC frame U-factors can be ~1 W/(m²·K) greater than their ISO *Standard* 10077-2 equivalents. Although such differences are diluted when a whole-system, area-weighted calculation is performed, it

Licensed for single user. © 2021 ASHRAE, Inc.

cannot be assumed that these differences are negligible in all cases. Use ISO *Standard* 10077-based U-factors with caution and, for code compliance purposes in the United States, Canada, Australia, and some other countries, seek certifications based on NFRC procedures and environmental conditions. Refer to building codes for detailed requirements concerning NFRC compliance.

3.1 DETERMINING FENESTRATION U-FACTORS

Center-of-Glass U-Factor

For single glazing, U-factors depend strongly on indoor and outdoor film coefficients. The U-factor for single glazing is

$$U_{single\ glazing} = \frac{1}{1/h_o + 1/h_i + L/k} \quad (3)$$

where

h_o, h_i = outdoor and indoor respective glazing surface heat transfer coefficients, W/(m²·K)
L = glazing thickness, m
k = thermal conductivity of glass, W/(m²·K)

For other fenestration, values for U_{cg} at standard indoor and outdoor conditions depend on glazing construction features such as the number of glazing lights, gas space dimensions, orientation relative to vertical, emissivity of each surface, and composition of fill gas. Several computer programs can be used to estimate glazing unit heat transfer for a wide range of glazing construction. The National Fenestration Rating Council (NFRC) calls for LBNL WINDOW 7.4 (LBNL 2016) as a standard calculation method for center of glazing.

Heat flow across the central glazed portion of a multipane unit must consider both convective and radiative transfer in the gas space, and may be considered one-dimensional. Convective heat transfer is estimated based on high-aspect-ratio, natural convection correlations for vertical and inclined air layers (El Sherbiny et al. 1982; Shewen 1986; Wright 1996a). Radiative heat transfer (ignoring gas absorption) is quantified using a more fundamental approach. Computational methods solving the combined heat transfer problem have been devised by Hollands and Wright (1982), Rubin (1982a, 1982b), and Rubin et al. (1998).

Figure 3 shows the effect of gas space width on U_{cg} for vertical double- and triple-paned glazing units. U-factors are plotted for air, argon, and krypton fill gases and for high (uncoated) and low (coated) values of surface emissivity. The optimum gas space width is 13 mm for air and argon, and 8 mm for krypton. Greater widths have no significant effect on U_{cg}. Greater glazing unit thicknesses decrease U_o because the length of the shortest heat flow path through the frame increases. A low-emissivity coating combined with krypton gas fill offers significant potential for reducing heat transfer in narrow-gap-width glazing units.

Edge-of-Glass U-Factor

The edge-of-glass area is typically taken to be a band 65 mm wide around the sightline. The width of this area is determined from the extent of two-dimensional heat transfer effects in current computer models, which are based on conduction-only analysis. In reality, because of convective and radiative effects, this area may extend beyond 65 mm (Beck et al. 1995; Curcija and Goss 1994; Wright and Sullivan 1995a), and depends on the type of glazing unit and its thickness. The edge region may also extend farther in opaque systems such as spandrel panels. The appropriate edge width to use can be determined using finite-element heat transfer modeling, as described by Curcija and Goss (1994).

In low-conductivity frames, most heat flow at the edge-of-glass and frame area is through the spacer, so the type of spacer has a greater impact on the edge-of-glass and frame U-factor. In metal frames, the edge-of-glass and frame U-factor varies little with the type of spacer (metal or insulating) because there is a significant heat flow through the highly conductive frame near the edge-of-glass area.

Frame U-Factor

Fenestration frame elements consist of all structural members exclusive of glazing units and include sash, jamb, head, and sill members; meeting rails and stiles; mullions; and other glazing dividers. Estimating the rate of heat transfer through the frame is complicated by the (1) variety of fenestration products and frame configurations, (2) different combinations of materials used for frames, (3) different sizes available, and, to a lesser extent, (4) glazing unit width and spacer type. Internal dividers or grilles have little effect on the fenestration U-factor, provided there is at least a 3 mm gap between the divider and each glazing.

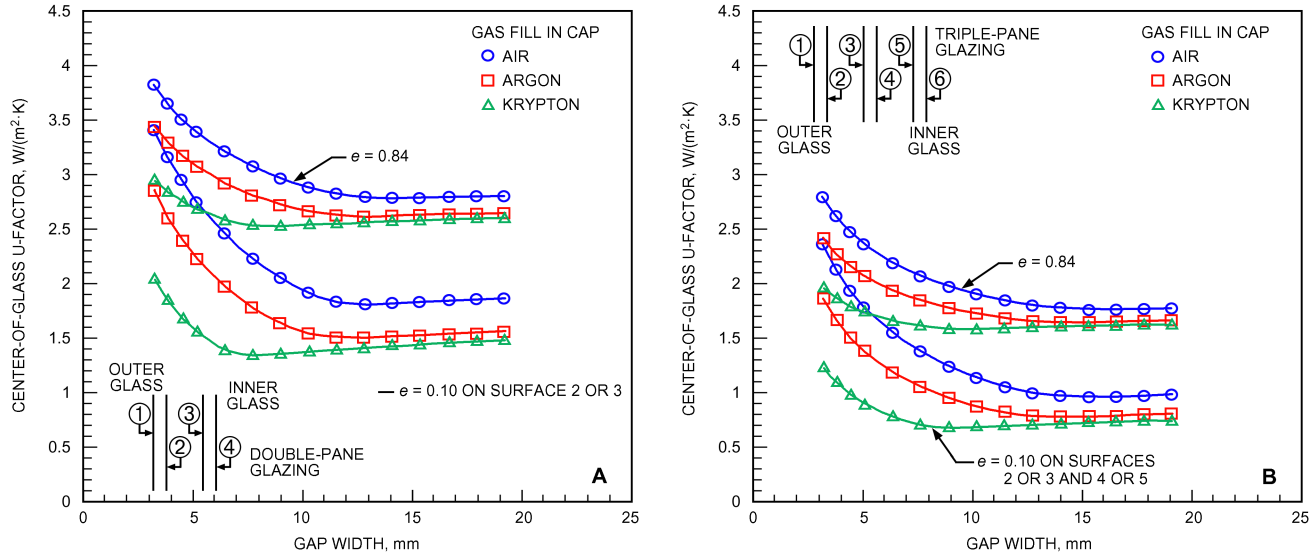

Fig. 3 Center-of-Glass U-Factor for Vertical Double- and Triple-Pane Glazing Units
Gas fill is assumed to be 90% argon, 10% air.

Computer simulations show that frame heat loss in most fenestration is controlled by a single component or controlling resistance, and only changes in this component significantly affect frame heat loss (EEL 1990). For example, the frame U-factor for thermally broken aluminum fenestration products is largely controlled by the depth of the thermal break material in the heat flow direction. For aluminum frames without a thermal break, the indoor film coefficient provides most of the resistance to heat flow. For vinyl- and wood-framed fenestrations, the controlling resistance is the shortest distance between the indoor and outdoor surfaces, which usually depends on the thickness of the sealed glazing unit.

Carpenter and McGowan (1993) experimentally validated frame U-factors for a variety of fixed and operable fenestration product types, sizes, and materials using computer modeling techniques. Table 1 lists frame U-factors for a variety of frame and spacer materials and glazing unit thicknesses. Frame and edge U-factors are normally determined by two-dimensional, finite-element computer simulation.

Curtain Wall Construction

A curtain wall is an exterior building wall that carries no roof or floor loads and consists entirely or principally of glass and other surfacing materials supported by a framework. A curtain wall typically has a metal frame. To improve the thermal performance of standard metal frames, manufacturers provide both traditional thermal breaks as well as thermally improved products. The traditional thermal break is poured and debridged (i.e., urethane is poured into a metal U-channel in the frame and then the bottom of the channel is removed by machine). For this system to work well, there must be a thermal break between indoors and outdoors for all frame components, including those in any operable sash. Skip debridging (incomplete pour and debridging used for increased structural strength) can significantly degrade the U-factor. Bolts that penetrate the thermal break also degrade performance, but to a lesser degree. Griffith et al. (1998) showed that stainless steel bolts spaced 300 mm on center increased the frame U-factor by 18%. The paper also concluded that, in general, the isothermal planes method referenced in Chapter 27 provides a conservative approach to determining U-factors.

Thermally improved metal curtain wall products are now being used more widely. In these products, most of the metal frame tends to be located on the indoor side with only a metal cap exposed on the outdoor side. Plastic spacers isolate the glazing assembly from both the outdoor metal cap and the indoor metal frame. These products can have significantly better thermal performance than standard metal frames, but it is important to minimize the number and area of the bolts that penetrate from outdoor to indoor. Curtain wall systems using structural silicone glazing (SSG) can also provide better thermal performance than dry-glazed bolted systems. Silicone sealants, with a typical thermal conductivity of 0.35 W/(m·K) and a dimension of 6 mm between the glass and aluminum are considered thermal breaks per NFRC *Technical Document* 100 (NFRC 2014a). Work by Carbary et al. (2009) demonstrates that SSG systems have lower U-factors than comparable nonbroken or thermally improved dry-glazed systems, resulting in frame temperatures closer to interior ambient conditions.

A more recent development is the use of fiberglass as the framing material for curtain walls. Fiberglass provides the strength needed for taller buildings while having a U-factor equal to or lower than that of other nonmetal materials (e.g., wood, vinyl).

An important consideration in any curtain wall system is durability. Sealants or gaskets that degrade or fail over time allow additional air infiltration, which negatively affects energy consumption. A durable system minimizes air infiltration and thereby energy consumption.

3.2 SURFACE AND CAVITY HEAT TRANSFER COEFFICIENTS

Part of the overall thermal resistance of a fenestration system derives from convective and radiative heat transfer between the exposed surfaces and the environment, and in the cavity between glazings. Surface heat transfer coefficients h_o, h_i, and h_c at the outer and inner glazing surfaces, and in the cavity, respectively, combine the effects of radiation and convection.

Wind speed and building orientation are important in determining h_o. This relationship has long been studied, and many correlations have been proposed for h_o as a function of wind speed. However, no universal relationship has been accepted, and limited field measurements at low wind speeds by Klems (1989) differ significantly from values used by others.

Convective heat transfer coefficients are usually determined at standard temperature and air velocity conditions on each side. Wind speed can vary from less than 0.2 m/s for calm weather, free convection conditions, to over 29 m/s for storm conditions. A nominal value of 26 W/(m²·K) corresponding to a 5.5 m/s wind is often

Table 2 Indoor Surface Heat Transfer Coefficient h_i in W/(m²·K), Vertical Orientation (Still Air Conditions)

		1.2	17	4	6.72	40	16	8.20
		1.8	17	4	6.53	40	16	7.94

Notes:
[a]Glazing ID refers to fenestration assemblies in Table 4.
[b]Winter conditions: room air temperature t_i = 21°C, outdoor air temperature t_o = –18°C, no solar radiation
[c]Summer conditions: room air temperature t_i = 24°C, outdoor air temperature t_o = 32°C, direct solar irradiance E_D = 748 W/m²
$h_i = h_{ic} + h_{iR} = 1.46(\Delta T/L)^{0.25} + \varepsilon\sigma(T_i^4 - T_g^4)/\Delta T$, where $\Delta T = T_i - T_g$, K; L = glazing height, m; T_g = glazing temperature, K; σ = Stefan-Boltzmann constant; and ε = surface emissivity.

used to represent winter design conditions. At low wind speeds, h_o varies with outdoor air and surface temperature, orientation to vertical, and air moisture content. The overall surface heat transfer coefficient can be as low as 6.8 W/(m²·K) (Yazdanian and Klems 1993).

For natural convection and radiation at the indoor surface of a vertical fenestration product, surface coefficient h_i depends on the indoor air and glazing surface temperatures and on the emissivity of the glazing surface. Table 2 shows the variation of h_i for winter (t_i = 21°C) and summer (t_i = 24°C) design conditions, for a range of glazing system types and heights. Designers often use h_i = 8.3 W/(m²·K), which corresponds to t_i = 21°C, a glazing temperature of –9.4°C, and emissivity of e_g = 0.84 (uncoated glass). For summer conditions, the same value [h_i = 8.3 W/(m²·K)] is normally used, and corresponds approximately to a glazing temperature of 35°C, t_i = 24°C, and e_g = 0.84. For winter conditions, this most closely approximates single glazing with clear glass that is 600 mm tall, but it overestimates the value as the glazing unit conductance decreases and height increases. For summer conditions, this value approximates all types of glass that are 600 mm tall but, again, is less accurate as glass height increases. If the indoor surface of the glass has a low-e coating, h_i values are about halved at both winter and summer conditions.

Heat transfer between the glazing surface and its environment is driven not only by local air temperatures but also by radiant temperatures to which the surface is exposed. The radiant temperature of the indoor environment is generally assumed to be equal to the indoor air temperature. This is a safe assumption where a small fenestration is exposed to a large room with surface temperatures equal to the air temperature, but it is not valid in rooms where the fenestration is exposed to other large areas of glazing surfaces (e.g., greenhouse, atrium) or to other cooled or heated surfaces (Parmelee and Huebscher 1947).

The radiant temperature of the outdoor environment is frequently assumed to be equal to the outdoor air temperature. This assumption may be in error, because additional radiative heat loss occurs between a fenestration and the clear sky (Berdahl and Martin 1984). Therefore, for clear-sky conditions, some effective outdoor temperature $t_{o,e}$ should replace t_o in Equation (1). For methods of determining $t_{o,e}$, see, for example, work by AGSL (1992). Note that a fully cloudy sky is assumed in ASHRAE design conditions.

The air space in a glazing unit constructed using glass with no reflective coating on the air space surfaces has a coefficient h_s of 7.4 W/(m²·K). When a reflective coating is applied to an air space surface, h_s can be selected from Table 3 by first calculating the effective air space emissivity $e_{s,e}$ by Equation (4):

$$e_{s,e} = \frac{1}{1/e_o + 1/e_i - 1} \tag{4}$$

where e_o and e_i are the hemispherical emissivities of the two air space surfaces. Hemispherical emissivity of ordinary uncoated glass is 0.84 over a wavelength range of 0.4 to 40 μm.

Table 4 lists computed U-factors, using winter design conditions, for a variety of generic fenestration products, based on ASHRAE-sponsored research involving laboratory testing and computer simulations. In the past, test data were used to provide more accurate results for specific products (Hogan 1988). Computer simulations (with validation by testing) are now accepted as the standard method for accurate product-specific U-factor determination. The simulation methodologies are specified in NFRC *Technical Document* 100 (NFRC 2014a) and are based on algorithms published in ISO *Standard* 15099. The *International Energy Conservation Code* and various state energy codes in the United States, the National Energy Code in Canada, and ASHRAE *Standards* 90.1 and 90.2 all reference these standards. Fenestration must be rated in accordance with the NFRC standards for code compliance. Use of Table 4 should be limited to that of an estimating tool for the early phases of design.

Values in Table 4 are for vertical installation and for skylights and other sloped installations with glazing surfaces sloped 20° from the horizontal. Data are based on center-of-glass and edge-of-glass component U-factors and assume that there are no dividers. However, they apply only to the specific design conditions described in the table's footnotes, and are typically used only to determine peak load conditions for sizing heating equipment. Although these U-factors have been determined for winter conditions, they can also be used to estimate heat gain during peak cooling conditions, because conductive gain, which is one of several variables, is usually a small portion of the total heat gain for fenestration in direct sunlight. Glazing designs and framing materials may be compared in choosing a fenestration system that needs a specific winter design U-factor.

Table 4 lists 48 glazing types, with multiple glazing categories appropriate for sealed glazing units and the addition of storm sash to other glazing units. No distinction is made between flat and domed units such as skylights. For acrylic domes, use an average gas-space width to determine the U-factor. Note that garden window and sloped/pyramid/barrel vault skylight U-factors are approximately twice those of other similar products. Although this is partially because of the difference in slope in the case of sloped/pyramid/barrel vault skylights, it is largely because these products project out

from the surface of the wall or roof. For instance, the skylight surface area, which includes the curb, can vary from 13 to 240% greater than the rough opening area, depending on the size and mounting method. Unless otherwise noted, all multiple-glazed units are filled with dry air. Argon units are assumed to be filled with 90% argon (Elmahdy and Yusuf 1995). U-factors for CO_2-filled units are similar to argon fills. For spaces up to 13 mm, argon/SF_6 (sulfur hexafluoride) mixtures up to 70% SF_6 are generally the same as argon fills. Use of krypton gas can provide U-factors lower than those for argon for glazing spaces less than 13 mm.

Table 4 provides data for six values of hemispherical emissivity and for 6 and 13 mm gas space widths. Emissivity of various low-e glasses varies considerably between manufacturers and processes. When emissivity is between the listed values, interpolation may be used. When manufacturers' data are not available for low-e glass, assume that glass with a pyrolytic (hard) coating has a maximum emissivity of 0.20 and that glass with a sputtered (soft) coating has a maximum emissivity of 0.10. Tinted glass does not change the winter U-factor. Also, some surface-coated reflective glass may have an emissivity less than 0.84. Values listed are for glass units using aluminum edge spacers. If an insulated or nonmetallic spacer is used, the U-factors are approximately 0.17 W/(m²·K) lower.

Fenestration product types are subdivided first by vertical versus sloped installation and then into two general categories: manufactured and site assembled. **Manufactured products** are delivered as complete units to the site. These products are typically installed in low-rise residential and small commercial/institutional/industrial buildings. Use the operable category for vertical sliders, horizontal sliders, casement, awning, pivoted, and dual-action windows, and for sliding and swinging glass doors. For picture windows, use the fixed category. For products that project out from the surface of the wall, use the garden window category. For skylights, use the sloped skylight category.

Site-assembled products have frame extrusions that are assembled on site, and then glazing is added. These products are typically installed in high-rise residential and larger commercial/institutional/industrial buildings. Curtain walls are typically made up of vision (transparent) and spandrel (opaque) panels. Table 4 contains representative U-factors for the vision panel (including mullions) for these assemblies. The spandrel portion of curtain walls usually consists of a metal pan filled with insulation and covered with a sheet of glass or other weatherproof covering. Although the U-factor in the center of the spandrel panel can be quite low, the metal pan is a thermal bridge, significantly increasing the U-factor of the assembly. Two-dimensional simulation, validated by testing of a curtain wall having an aluminum frame with a thermal break, found that the U-factor for the edge of the spandrel panel (the 65 mm band around the perimeter adjacent to the frame) was 40% of the way toward the U-factor of the frame. The U-factor was 0.34 W/(m²·K) for the center of the spandrel, 2.56 for the edge of the spandrel, and 6.02 for the frame (Carpenter and Elmahdy 1994). Two-dimensional heat transfer analysis or physical testing is recommended to determine the U-factor of spandrel panels. Use the sloped/overhead glazing category for sloped glazing panels comparable to curtain walls.

Physical testing of double-glazed units showed U-factors of 5.74 W/(m²·K) for a thermally broken aluminum pyramidal skylight and 7.4 W/(m²·K) for an aluminum-frame half-round barrel

Notes:

1. All heat transmission coefficients in this table include film resistances and are based on winter conditions of –18°C outdoor air temperature and 21°C indoor air temperature, with 6.7 m/s outdoor air velocity and zero solar flux. Except for single glazing, small changes in the indoor and outdoor temperatures do not significantly affect overall U-factors. Coefficients are for vertical position except skylight values, which are for 20° from horizontal with heat flow up.
2. Glazing layer surfaces are numbered from outdoor to indoor. Double, triple, and quadruple refer to number of glazing panels. All data are based on 3 mm glass, unless otherwise noted. Thermal conductivities are: 0.917 W/(m·K) for glass, and 0.19 W/(m·K) for acrylic and polycarbonate.
3. Standard spacers are metal. Edge-of-glass effects are assumed to extend over the 63.5 mm band around perimeter of each glazing unit.

4. Product sizes are described in Figure 4, and frame U-factors are from Table 1.
5. Use $U = 3.40$ W/(m²·K) for glass block with mortar but without reinforcing or framing.
6. Use of this table should be limited to that of an estimating tool for early phases of design.
7. Values for triple- and quadruple-glazed garden windows are not listed, because these are not common products.
8. U-factors in this table were determined using NFRC 100-91. They have not been updated to the current rating methodology in NFRC 100 (2014a).

Fig. 4 Frame Widths for Standard Fenestration Units

vault (both normalized to a rough opening of 2.4 by 2.4 m). Until more conclusive results are available, U-factors for these systems can be estimated by multiplying the site-assembled sloped/overhead glazing values in Table 4 by the ratio of total product surface area (including curbs) to rough opening area. These ratios range from 1.2 to 2.0 for low-slope skylights, 1.4 to 2.1 for pyramid assemblies sloped at 45°, and 1.7 to 2.9 for semicircular barrel vault assemblies.

U-factors in Table 4 are based on definitions of the six product types, frame sizes, and proportion of frame to glass area shown in Figure 4. Four of the products are manufactured type. Sizes are as defined in NFRC *Technical Document* 100 (2014a): operable and fixed (nonoperable) glazing units are 1.8 m^2 in area, and the overall size corresponds to a 1200 by 1500 mm fenestration product. The garden window category is 1.8 m^2 in projected area (3.24 m^2 in surface area) and 1500 mm wide by 1200 mm high by 380 mm deep. The manufactured skylight category is a nominal 1.44 m^2 in area, corresponding to a 1200 by 1200 mm skylight. The nominal dimensions of a roof-mounted skylight correspond to centerline spacing of roof framing members; consequently, the rough opening dimensions are 1180 by 1180 mm. The curtain wall and sloped/overhead glazing categories are a nominal 4 m^2 in area, representing repeating 2000 by 2000 mm panels. The nominal dimensions correspond to centerline spacing of the head and sill and vertical mullions.

Six frame types are listed (although not all for any one category) in order of improving thermal performance. The most conservative assumption is to use the frame category of aluminum frame without a thermal break (although there are products on the market that have higher U-factors). The aluminum frame with a thermal break is for frames having at least a 10 mm thermal break between the indoors and outdoors for all members including both the frame and the operable sash, if applicable. Some products are available with significantly wider thermal breaks, which achieve considerable improvement. The aluminum-clad wood/reinforced vinyl category represents vinyl-frame products, such as sliding glass doors or large windows that have extensive metal reinforcing within the frame and wood products with extensive metal, usually on the outdoor surface of the frame. Both of these factors provide short circuits, which degrade the thermal performance of the frame material. The wood/vinyl frame category represents the improved thermal performance that is possible if the thermal short circuits from the previous frame category do not exist. Insulated fiberglass/vinyl represents fiberglass or vinyl frames that do not have metal reinforcing and whose frame cavities are filled with insulation. For several site-assembled product types, there is a structural glazing frame category that represents products where sheets of glass are butt-glazed to each other using a sealant only, and framing members are not exposed to the exterior. For glazing with a steel frame, use aluminum frame values. For aluminum fenestration with wood trim or vinyl cladding, use the values for aluminum. Frame type refers to the primary unit; therefore, when storm sash is added over another fenestration product, use values given for the nonstorm product.

Table 5 Glazing U-Factors for Various Wind Speeds in W/(m^2·K)

Wind Speed, km/h		
24	12	0
0.5	0.46	0.42
1.0	0.92	0.85
1.5	1.33	1.27
2.0	1.74	1.69
2.5	2.15	2.12
3.0	2.56	2.54
3.5	2.98	2.96
4.0	3.39	3.38
4.5	3.80	3.81
5.0	4.21	4.23
5.5	4.62	4.65
6.0	5.03	5.08
6.5	5.95	5.50

To estimate the overall U-factor of a fenestration product that differs significantly from the assumptions given in Table 4 and/or Figure 4, first determine the area that is frame/sash, center-of-glass, and edge-of-glass (based on a 63.5 mm band around the perimeter of each glazing unit). Next, determine the appropriate component U-factors. These can be taken either from the standard values listed in italics in Table 4 for glass, from the values in Table 1 for frames, or from some other source such as test data or computed factors. Finally, multiply the area and the component U-factors, sum these products, and then divide by the rough opening

Licensed for single user. © 2021 ASHRAE, Inc.

in the building envelope where this product will fit to obtain the overall U-factor U_o.

Table 5 provides approximate data to convert the overall U-factor at one wind condition to a U-factor at another.

Example 1. Estimate the design U-factor for a manufactured fixed fenestration product with a reinforced vinyl frame and double-glazing with a sputter-type low-e coating (e = 0.10). The gap is 13 mm wide and argon-filled, and the spacer is metal. The outdoor wind speed is 12 km/h.

Solution: Locate the glazing system type in the first column of Table 4 (ID = 23), then find the appropriate product type (fixed) and frame type (reinforced vinyl). The U-factor listed (in the tenth column of U-factors) is 1.86 W/(m²·K). This U-factor is for 24 km/h outdoor wind speed.

From Table 5, interpolate 1.86 in the 24 km/h column to the corresponding value in the 12 km/h column.

$$\frac{1.86 - 1.50}{2.00 - 1.50} = \frac{U_{12\ km/h} - 1.33}{1.74 - 1.33}$$

$$U_{12\ km/s} = 1.63\ W/(m^2 \cdot K)$$

Example 2. Estimate a representative U-factor for a wood-framed, 970 by 2080 mm swinging French door with eight 280 by 400 mm panes (true divided panels), each consisting of clear double-glazing with a 6.5 mm air space and a metal spacer.

Solution: Without more detailed information, assume that the dividers have the same U-factor as the frame and that the divider edge has the same U-factor as the edge-of-glass. Calculate center-of-glass, edge-of-glass, and frame areas:

$$A_{cg} = 8[(280 - 130)(400 - 130)]/10^6 = 0.324\ m^2$$

$$A_{eg} = 8(280 \times 400)/10^6 - 0.324 = 0.572\ m^2$$

$$A_f = (970 \times 2080)/10^6 - 8(280 \times 400)/10^6 = 1.122\ m^2$$

Select center-of-glass, edge-of-glass, and frame U-factors. These component U-factors are 3.12 and 3.63 W/(m²·K) (from Table 4, glazing ID = 4, U-factor columns 1 and 2) and 2.90 W/(m²·K) (from Table 1, wood frame, metal spacer, operable, double-glazing), respectively. From Equation (2),

$$U_{french\ door} = \frac{(3.12 \times 0.324) + (3.63 \times 0.572) + (2.90 \times 1.122)}{(0.97 \times 2.08)}$$

$$= 3.14\ W/(m^2 \cdot K)$$

Example 3. Estimate the overall average U-factor for a multifloor curtain wall assembly that is part vision glass and part opaque spandrel. The typical floor-to-floor height is 3.6 m, and the building module is 1.2 m as reflected in the spacing of the mullions both horizontally and vertically. For a representative section 1.2 m wide and 3.6 m tall, one of the modules is glazed and the other two are opaque. The mullions are aluminum frame with a thermal break 80 mm wide and centered on the module. The glazing unit is double glazing with a pyrolytic low-e coating (e = 0.40) and has a 13 mm gap filled with air and a metal spacer. The spandrel panel has a metal pan backed by R = 3.5 (m²·K)/W insulation and no intermediate reinforcing members.

Solution: It is necessary to calculate the U-factor for the glazed module and for the opaque spandrel modules, and then to do an area-weighted average to determine the average U-factor for the overall curtain wall assembly.

First, calculate the overall U-factor for the glazed module. Calculate center-of-glass, edge-of-glass, and frame areas. The glazed area is 1120 by 1120 mm (1200 mm module, 38 mm of mullions on each edge).

$$A_{cg} = (1120 - 130)(1120 - 130)/10^6 = 0.9801\ m^2$$

$$A_{eg} = (1120 \times 1120)/10^6 - 0.9801 = 0.2743\ m^2$$

$$A_f = [(1200 \times 1200)/10^6 - (1120 \times 1120)]/10^6 = 0.1856\ m^2$$

Select center-of-glass, edge-of-glass, and frame U-factors. These component U-factors are 2.27 and 3.04 W/(m²·K) (from Table 4, ID = 13, columns 1 and 2) and 9.94 W/(m²·K) (from Table 1, aluminum frame with a thermal break, metal spacer, curtain wall, double glazing), respectively. From Equation (2),

$$U_{glazing\ module} = \frac{(2.27 \times 0.9801) + (3.04 \times 0.2743) + (9.94 \times 0.1856)}{(1.2 \times 1.2)}$$

$$= 3.41\ W/(m^2 \cdot K)$$

Then, calculate the overall U-factor for the two opaque spandrel modules. The center-of-spandrel, edge-of spandrel, and frame areas are the same as the glazed module. The frame U-factor is the same. Calculate the center-of-spandrel U-factor. In this particular case, the R-value of the insulation does not need to be rated, because there are no intermediate framing members penetrating it and providing thermal short circuits. When the resistance of the insulation [3.5 (m²·K)/W] is added to the exterior air film resistance of 0.03 (m²·K)/W and the interior air film resistance of 0.12 (m²·K)/W (from Table 1, Chapter 26), the total resistance is 3.65 (m²·K)/W, and the U-factor is 1/3.65 = 0.274 W/(m²·K). The edge-of-spandrel U-factor is 40% of the way to the frame U-factor, which is 0.274 + [0.40(9.94 –0.274)] = 4.14 W/(m²·K).

$$U_{opaque\ spandrel\ module} = \frac{(0.274 \times 0.9801) + (4.14 \times 0.2743) + (9.94 \times 0.1856)}{(1.2 \times 1.2)}$$

$$= 2.26\ W/(m^2 \cdot K)$$

Finally, calculate the overall average U-factor for the curtain wall assembly, including the one module of vision glass and the two modules of opaque spandrel.

$$U_{curtain\ wall} = \frac{[3.41 \times (1.2 \times 1.2)] + [2.26 \times 2 \times (1.2 \times 1.2)]}{3 \times (1.2 \times 1.2)}$$

$$= 2.64\ W/(m^2 \cdot K)$$

Note that even with double glazing having a low-e coating and with R = 3.5 (m²·K)/W in the opaque areas, this curtain wall with metal pans only has an overall R-value of approximately 0.38 (m²·K)/W.

Example 4. Estimate the U-factor for a semicircular barrel vault that is 6 m wide, 3 m tall, and 10 m long mounted on a 150 mm curb. The barrel vault has an aluminum frame without a thermal break. The glazing is double with a 13 mm gap width filled with air and a low-e coating (e = 0.20).

Solution: An approximation can be made by multiplying the U-factor for a site-assembled sloped/overhead glazing product having the same frame and glazing features by the ratio of the surface area (including the curb) of the barrel vault to the rough opening area in the roof that the barrel vault fits over. First, determine the surface area (including the curb) of the barrel vault:

Area of the curved portion of the barrel vault
= (π × diameter/2) × length
= (3.14 × 6/2) × 10 = 94.25 m²

Area of the two ends of the barrel vault
= 2 × (π × radius²)/2 = πr^2
= 3.14 × 3² = 28.27 m²

Area of the curb
= perimeter × curb height
= (6 + 10 + 6 + 10) × 0.150 = 4.8 m²

Total surface area of the barrel vault
= 94.25 + 28.27 + 4.8 = 127.3 m²

Second, determine the rough opening area in the roof that the barrel vault fits over:
= length × width
= 6 × 10 = 60 m²

Third, determine the ratio of the surface area to the rough opening area:
= 127.3/60 = 2.12

Fourth, determine the U-factor from Table 4 of a site-assembled sloped/overhead glazing product having the same frame and glazing features.

Licensed for single user. © 2021 ASHRAE, Inc.

The U-factor is 3.51 W/(m²·K) (ID = 17, 12th column on the second page of Table 4).

Fifth, determine the estimated U-factor of the barrel vault.

$U_{barrel\ vault}$
= $U_{sloped\ overhead\ glazing}$ × surface area/rough opening for the barrel vault
= 3.51 × 2.12 = 7.44 W/(m²·K)

3.3 REPRESENTATIVE U-FACTORS FOR DOORS

Doors are often an overlooked component in the thermal integrity of the building envelope. Although entry doors (swinging, revolving, etc.) represent a small portion of the building envelope of residential, commercial, and institutional buildings, their U-factor is usually many times higher than that of the walls or ceilings. In some commercial and industrial buildings, vehicular access doors (upward-acting doors) represent a significant area of heat loss. Table 6 contains representative U-factors for swinging doors determined through computer simulation (Carpenter and Hogan 1996). These are generic values, and product-specific values determined in accordance with standards should be used whenever available. NFRC *Technical Documen*t 100 (NFRC 2014a) gives procedures for evaluating the performance of entry and vehicular access doors. Tables 7 to 9 contain representative U-factors for revolving, emergency exit, garage, and aircraft hangar doors determined through testing (McGowan et al. 2006).

Swinging doors can be divided into two categories: slab and stile-and-rail. A stile-and-rail door is a swinging door with a full-glass insert supported by horizontal rails and vertical stiles. The stiles and rails are typically either solid wood members or extruded aluminum or vinyl, as shown in Figure 5. Most residential doors are slab type with solid wood, steel, or a fiberglass skin over foam insulation in a wood frame with aluminum sill. The edges of the steel skin door are normally wood to provide a thermal break. In commercial construction, doors are either steel skin over foam insulation in a steel frame (i.e., utility doors) or a full glass door made up of aluminum stiles, rails, and frame (i.e., entrance doors). The most important factors affecting door U-factor are material construction, glass size, and glass type. Frame depth, slab width, and number of panels have a minor effect on door performance. Side lites and double doors have U-factors similar to a single door of the same construction. For wood slab doors in a wood frame, the glazing area has little effect on the U-factor. For an insulated steel slab in a wood frame, however, glazing area strongly affects U-factor. Typical commercial insulated slab doors have a U-factor approximately twice that of residential insulated doors, the prime reason being thermal bridging of the slab edge and the steel frame. Stile-and-rail doors, even if thermally broken, have U-factors 50% higher than a full-glass commercial steel slab door.

There are three generic types of upward-acting doors:

- Rolling (also called roll-up) doors consist of small metal slats of approximately 65 mm in height that travel in vertical guides and roll up around a metal barrel to open.
- Sectional (also called garage) doors consist of a series of approximately 460 to 815 mm high sections that travel in vertical tracks to open.
- Folding (also called biparting) doors, commonly used in aircraft hangars, have two large sections that also travel in vertical tracks to open, but fold together when the door is fully open.

There is a wide range in the design of insulated upward-acting doors. Factors affecting heat transfer include insulation thickness, section/slat design, and section/slat interface design (which may

include a thermal break). For noninsulated upward-acting doors, there is very little difference between the center value and the total value: the value is essentially equal to that of single glazing. The center of an insulated door has a relatively low U-factor, but thermal bridging at the door frame and section interfaces can affect the door assembly U-factor. Center-of-door U-factors for vehicular access doors may be used in thermal calculations for buildings only if the door design or door size indicates little difference with respect to the total door assembly U-factor.

Many commercial buildings use revolving entrance doors. Most of these doors are of similar design: single glazing in an aluminum frame without thermal break. The door, however, can be in two positions: closed (X-shaped as viewed from above) or open (+-shaped as viewed from above). At nighttime, these doors are locked in the X position, effectively creating a double-glazed system. During the daytime, the door revolves and is often left positioned so that there is only one glazing between the indoors and outdoors (+ position). U-factors are given in Table 7 for both positions.

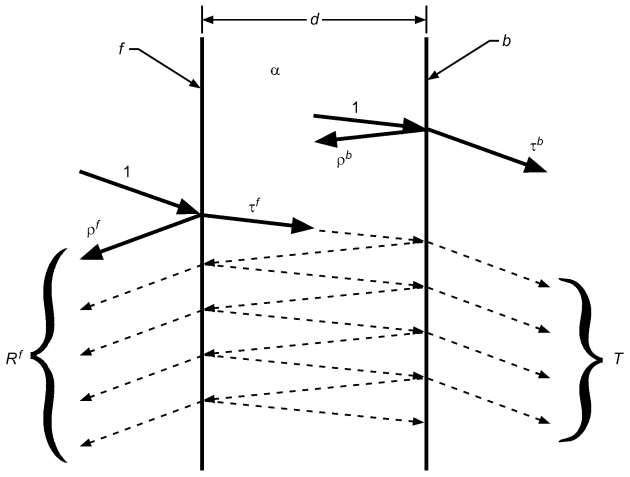

Fig. 6 Optical Properties of a Single Glazing Layer

4. SOLAR HEAT GAIN AND VISIBLE TRANSMITTANCE

Fenestration solar heat gain has two components. First is **directly transmitted solar radiation**. The quantity of radiation entering the fenestration directly is governed by the solar transmittance of the glazing system, and is determined by multiplying the incident irradiance by the glazing area and its solar transmittance. The second component is the inward flowing fraction of **absorbed solar radiation**, radiation that is absorbed in the glazing and framing materials of the fenestration, some of which is subsequently conducted, convected, or radiated to the interior of the building.

Visible transmittance is the solar radiation transmitted through fenestration weighted with respect to the photopic response of the human eye. It physically represents the perceived clearness of the fenestration, and is likely different from the solar transmittance of the same fenestration.

The underlying physics behind solar heat gain and visible transmittance can be very complex, but a rudimentary understanding is required if technologies such as low-e coatings are to be discussed. Accurately calculating the solar heat gain and visible transmittance of a fenestration system, including the effects of angular and spectral dependence, in the presence of multiple glazing and shade layers, is very complex. Refer to ISO *Standard* 15099 or the ASHRAE Handbook Online supplemental features for this chapter for complete details of how to do this calculation. Software such as LBNL WINDOW 7 (LBNL 2016) incorporate these advanced calculations and can be used for more detailed fenestration analysis.

4.1 SOLAR-OPTICAL PROPERTIES OF GLAZING

Optical Properties of Single Glazing Layers

Radiation passing from one medium into another is partly transmitted and partly reflected at the interface between the two media. Further, as this radiation passes through either medium, an additional fraction is absorbed because of the absorptivity of the material. Materials that do not absorb radiation completely, such as air or glass, are classified as being transparent or translucent. Translucent glazings exhibit sufficient light-diffusing properties that images of objects viewed through it are blurred. Opaque glazings transmit no perceptible light.

Licensed for single user. © 2021 ASHRAE, Inc.

Licensed for single user. © 2021 ASHRAE, Inc.

If solar radiation incident on glazing is considered, the **transmittance** T, **reflectance** R, and **absorptance** $\mathcal{A}$ of the glazing layer contain the effects of multiple reflections between the two interfaces of the layer as well as the effects of absorption during the passage through the layer of each interreflection (Figure 6). For radiation incident on the front side of the glazing, the reflectance is called the **front reflectance** R^f. The **back reflectance** R^b (not shown in Figure 6) is the reflectance of the layer for radiation incident on back side b.

The transmittance, reflectance, and absorptance of a layer are formally defined as the fractions of incident flux that transmit, reflect, and are absorbed by the layer, respectively, including the effects of interreflection. Their sum equals unity, as shown in Equation (5).

$$T + R + \mathcal{A} = 1 \tag{5}$$

The layer has a thickness d and is characterized by **transmissivity** τ and **reflectivity** ρ of each of the two surfaces and by the **absorptivity** α of the glazing layer of thickness d. In general, τ and ρ are characteristics of the interface between the material and the adjacent medium; they may in principle be different for the two surfaces (e.g., for a coated surface, or where a material layer is adjacent to another material rather than air). Physical arguments, however, dictate that T^f and T^b for the layer be the same (and the f and b superscripts are therefore omitted). R^f and R^b will be different given similar variations in coatings or adjacent materials, and examination of Equation (5) shows that $\mathcal{A}^f$ and $\mathcal{A}^b$ may be different as well. Uncoated glass has the same front and back properties.

Angular Variations. The interfacial properties τ and ρ, and consequently layer properties T, R, and $\mathcal{A}$, also depend on the incident angle θ of the radiation incident on the layer. Figure 7 shows the optical properties of common window glass as a function of incidence angle. This variation of properties is small for incident angles below 40° but becomes significant at larger angles. Chapter 14 provides details on calculating the direction and magnitude of solar flux that is incident on a glazing system.

Rubin (1985) measured broadband transmittance and reflectances for many uncoated (monolithic) glass substrates, including tinted substrates at various thicknesses. These formed the basis for Figure 8, which compares the properties of glasses of different thickness and composition. As the incident angle increases from zero, transmittance decreases, reflectance increases, and absorptance first increases because of the lengthened optical path and then decreases as more incident radiation is reflected. Although the shapes of the property curves are superficially similar, note that both the magnitude of the transmittance at normal incidence and the angle at which the transmittance changes significantly vary with glass type and thickness.

Wong (2016) normalized the measured solar transmittance (Rubin 1985) for 6 mm substrates. Two distinct sets of regressions coefficients appear to be adequate to represent the angular variation for a wide range of clear and tinted substrates. The result of the normalization is shown in Figure 9. These two distinct sets of regression coefficients were incorporated into the then WINDOW4 program (Finlayson et al. 1994) and all subsequent versions of that software. Note that tinted substrates considered here do not have as strong a spectrally selectively behavior as the high-performance tints described in Carmody et al. (2004).

The three curves all have slightly different shapes. For coated glasses or for multiple-pane glazing systems, this difference is more pronounced. One cannot assume that all glazings or glazing systems have a universal angular dependence.

ADOPT (1996) is a two-parameter model that describes the angular-dependent optical properties of glazing systems. It has been validated (Karlsson et al. 2001) against actual measurements (Rubin et al. 1999). Models have been developed from the ADOPT project, and validation of its accuracies at discrete angles of incidence had been reported (Hutchins et al. 2001; Rubin et al. 1998). The Simple Window Model (Arasteh et al. 2009) offers correlations for single-, double-, and triple-glazed systems for use in building energy simulation. The normalized transmittance curve is shown in Figure 10 below.

Angular performance is important when peak gains and annual energy performance are considered. In North America, peak summertime solar gains occur with east- and west-facing vertical

(McCluney 1996)

glazings at angles of incidence ranging from about 25 to 55°. The peak solar gain for horizontal glazings occurs typically at relatively small angles of incidence (midday sun high in sky in summer). For north- and south-facing vertical glazings, peak summertime solar gains occur at angles of incidence greater than about 40°. Angles of incidence important for annual energy performance calculations range from 5° to over 80° for east- and west-facing vertical and for horizontal glazings. This range is only slightly diminished for south-facing glazings. For north-facing glazings, the direct beam solar gains are small and their angles of incidence range from 62 to 86° (McCluney 1994a).

Spectral Variations. Many glazing systems have optical properties that are *spectrally selective* (i.e., they vary across the electromagnetic spectrum with wavelength λ). Ordinary clear float glass possesses this property, but to a modest degree that is seldom of much concern in load calculations. Tinted and coated glass can exhibit strong spectral selectivity, a desirable property for certain applications, and this effect must be accounted for in solar heat gain determinations.

Figure 11 (McCluney 1993) shows the normal incidence spectral transmittances of several common commercially available glazings. Figure 12 (McCluney 1996) shows the normal incidence spectral transmittances and outdoor reflectances of a variety of additional coated and tinted glasses, indicating the strong spectral selectivity now available from some glass and window manufacturers. Actual transmittance varies with the amount of iron or other absorbers in the glass. Uncoated glass with low iron content has a relatively constant spectral transmittance over the entire solar spectrum.

Solar-Optical Property Data. Transmittance and reflectance ar e the basic measurable quantities for an isolated glazing layer in air. Measurements on glazing layers are typically made using a spectrophotometer at normal or near-normal incidence, and the properties at other angles must be inferred from these measurements. A systematic compilation of these measured properties (for most glazings manufactured in the United States) called the International Glazing Database (IGDB) is maintained by the National Fenestration Rating Council and is available on the Internet at www.nfrc.org or from windows.lbl.gov/materials/IGDB/default.htm (LBNL 2016; NFRC 2014b). For uncoated glazings, layer properties can also be determined from first principles [e.g., McCluney (1994b)].

Advances in modeling complex glazing layers (e.g., screens, woven shades, blinds, some types of drapes) have led to the establishment of the Complex Glazing Database (CGDB 2016). Designed to support the LBNL (2016) WINDOW program and similar software, the CGDB contains detailed information on the angular and spectral properties of such materials, for total and diffuse transmittance and reflectance. The CGDB is being expanded to include products from many international manufacturers. More information may be found in the section on Shading and Fenestration Attachments.

Obtaining the necessary basic information about the solar-optical properties of coated glass requires spectrophotometric measurements. Alternatively, an approximation procedure is described by Finlayson and Arasteh (1993). Coated glazing properties should vary from these estimates by no more than ±20% at 60° incidence (Rubin et al. 1999). It is currently not practical to determine the solar-optical properties of coated glazings from first principles.

Optical Properties of Glazing Systems

The optical properties of glazing systems (multiple glazing layers) are affected by interreflections between layers in addition to the specular and angular properties of the individual layers.

Licensed for single user. © 2021 ASHRAE, Inc.

Consequently, the effect of a particular layer on the overall properties may not only depend on its solar-optical properties, but also on its position in the assembly. It is therefore necessary to expand glazing layer considerations to apply to the overall properties of systems and subsystems of glazing layers. The properties of any subsystem can be calculated by using recursion relations (LBNL 2016).

Spectral Averaging of Glazing System Properties. The solar-optical properties of a glazing are the wavelength-integrated (or total) transmittance, reflectance, and absorptance of the glazing to incident solar radiation. If the spectral optical properties $T(\lambda)$, $R(\lambda)$, and $\mathcal{A}(\lambda)$ of the glazing and the spectral irradiance $E(\lambda)$ incident on the glazing are known, the solar optical properties can be calculated using ASTM *Standards* E971, E972, and E1084, as well as NFRC *Technical Document* 300 (NFRC 2014c).

$$X = \frac{\int_{\lambda_{min}}^{\lambda_{max}} E_{STD}(\lambda) X(\lambda) d\lambda}{\int_{\lambda_{min}}^{\lambda_{max}} E_{STD}(\lambda) d\lambda} \tag{6}$$

where

$X(\lambda)$ = $T(\lambda)$, $R(\lambda)$, or $\mathcal{A}(\lambda)$
$E_{STD}(\lambda)$ = standard solar distribution
X = total T, R, or $\mathcal{A}$ to standard solar distribution

For multiple-layer glazing systems, the spectral averaging should in general be applied to the system spectral properties at each angle. Because all glazing layer properties are to some extent both angle and wavelength dependent, and because these equations are nonlinear in the glazing properties, this is the only procedure that is valid in principle.

Many glazings do not have strong spectral selectivity over the solar spectrum, so their spectral optical properties can be considered constant, even if the source spectrum changes substantially. In these cases, the transmitted spectral irradiance can be determined by multiplying the incident irradiance by the solar transmittance obtained with the standard solar distribution. For special combinations of climate and location, it may be desirable to use variant solar spectra as weighting functions, which requires an appropriate spectral solar radiation model (Gueymard 2007). It is still difficult, and seldom necessary, to perform radiative calculations using a detailed, time-dependent solar spectrum and the spectral glazing properties. Such additional calculations might only be justified in the case of glazings with strong spectral selectivity (Gueymard and DuPont 2009).

Angular Averaging of Glazing System Properties. It is relatively simple to account for angular dependence in beam solar radiation, because at a given time the radiation is incident from a single, easily determined direction. However, for diffuse solar and ground-reflected radiation, the situation is more complicated. In principle, energy flow through the glazing should equal the sum of individual energy flows caused by incident radiation from each direction.

Although such calculations can be done for specific sky conditions using detailed sky data or models, the labor involved is worthwhile only for very specific purposes. Usually, a drastically simplifying assumption is made. Both sky and ground radiation are assumed to be **ideally diffuse** (i.e., to have a sky radiance that is independent of direction). Diffuse properties are then determined by integrating over all directions. See the section on Diffuse Radiation under Solar Heat Gain Coefficient for more details. In addition, the spectral dependence is assumed to be the same as for beam solar radiation.

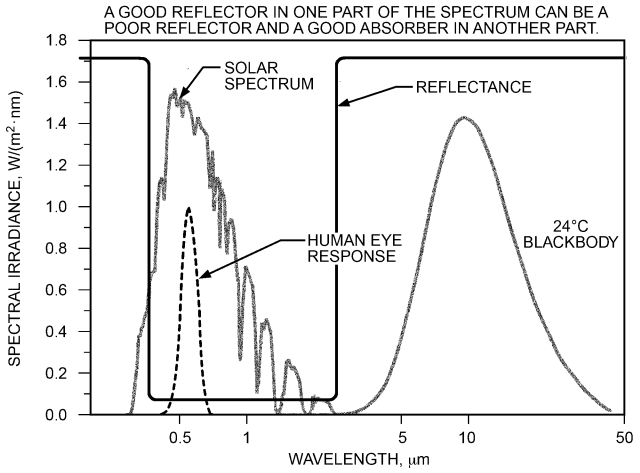

Fig. 13 Solar Spectrum, Human Eye Response Spectrum, Scaled Blackbody Radiation Spectrum, and Idealized Glazing Reflectance Spectrum

$$X_D = \frac{\iint_{hem} X(\theta)\cos\theta d\varpi}{\iint_{hem} \cos\theta d\varpi} = 2\int_0^{\pi/2} X(\theta)\cos\theta d\theta \tag{7}$$

where

$X(\theta)$ = $T(\theta)$, $R(\theta)$, or $\mathcal{A}(\theta)$
ϖ = solid angle of integration
X_D = total T, R, or $\mathcal{A}$ of standard solar distribution

More careful consideration must be given to these quantities for tilted glazings or for direction-dependent shading (e.g., overhangs, venetian blinds) when greater accuracy is desired.

Spectrally Selective Glazing and Glazing Systems. Spectrally selective glazing shows strong changes in its optical properties with variations in wavelength over the spectrum. The spectral range from 300 nm to over 50 μm contains radiation from both the sun and sky incident on fenestration systems. The majority of this radiation is called **short-wave** or **solar** radiation. About 99% of the energy in the solar spectrum is between 0.3 to 3.5 μm. The spectral range from 3.5 to over 50 μm is called **long-wave**, **infrared**, or **thermal** radiation, which contains radiation from the sun and sky, but also from warm bodies both outside and inside the building. In Figure 13, the solar spectrum for an air mass m = 1.5 (corresponding to a solar altitude of 41.8°) represents short-wave radiation, with thermal radiation represented by a blackbody source at 24°C. The latter has been scaled up to better compare it with the shape of the solar spectrum. The reflectance spectrum shown is an idealization of typical glazing reflectance. Figure 13 clearly shows the separation of the solar spectrum from the long-wave spectrum characteristic of radiant emission from an indoor pane of a multiple-pane glazing system.

Figure 13 also shows the human eye spectral response (called the human photopic visibility function). To the human eye, the glazing represented in the figure does not appear very reflective. It is also strongly transmitting for solar radiation, including the visible portion. The glazing is, however, nearly opaque to long-wave radiation, demonstrating that visual perception of a material is a poor indicator of its overall spectral characteristics. The glazing system reflectance depicted in Figure 13 is good for admitting solar radiation while preventing the escape of long-wave radiation emitted by surfaces inside the room, a good design for cold sunny days.

Licensed for single user. © 2021 ASHRAE, Inc.

Almost all window glass is opaque to long-wave radiation emitted by surfaces at temperatures below about 1200°C. This characteristic produces the **greenhouse effect**, by which solar radiation passing through fenestration is partially retained indoors by the following mechanism. Radiation absorbed by surfaces in the room is emitted as long-wavelength radiation, which cannot escape directly through the glass because of its opaqueness to radiation beyond 4.5 µm. Instead, radiation from room surfaces is absorbed and reemitted to both sides as determined by several parameters, such as the indoor and outdoor film heat transfer coefficients, the surface emissivities, and other glazing properties.

A good long-wave reflector can be a poor short-wave reflector and a good short-wave transmitter. Because of the conservation of energy ($T + R + \mathcal{A} = 1.0$), high long-wave reflectance means low transmittance and absorptance. Kirchhoff's law shows that low absorptance means low emissivity as well. This is the principle of operation of the high-solar-gain (or cold-climate) **low-e coating** on glass. Such a coating has high transmittance over the entire solar spectrum, producing high solar heat gain while being highly reflective to long-wave infrared radiation emitted by the indoor surfaces, reflecting this radiation inward. The term *low-e* refers to a low emissivity over the long-wavelength portion of the spectrum.

Figure 14 shows hypothetical glazing systems with performance tuned to specific climates. In this case, the sharp **reflectance edge** that the ideal high-solar-gain, cold-climate low-e coating exhibits just past the end of the solar spectrum in Figure 13 is shifted closer to the edge of the visible portion of the spectrum, thereby increasing the solar near-infrared (NIR) reflectance of the glazing. This results in a drop in the hot-climate transmittance to the right of the visible portion of the spectrum. The effect is to reflect the near-infrared portion of the solar spectrum outdoors, reducing solar gain, while still admitting visible light in the wavelength region below about 0.8 µm. This low-solar-gain, hot-climate coating also exhibits low emissivity over the long-wave spectrum, and is therefore also properly termed a low-e coating. To distinguish the cold- from the hot-climate version, a glazing with this type of spectral response is often termed **selective low-e**. This is something of a misnomer, because both hot- and cold-climate glazings are spectrally selective. Another term is **high-solar-gain, low-e** glazing system for cold climates, contrasted with **low-solar-gain, low-e** glazing system for hot climates.

The reduced infrared transmittance for the hot-climate glazing is ideally achieved by high reflectance and low absorptance (meaning also low emissivity). It can also be done with high infrared absorptance, if the flow of absorbed solar radiation to the interior of the building can be reduced, introducing a second approach to the construction of a hot-climate, low-solar-gain glazing system. In this case, the outer pane of a multiple-pane glazing system is made to have good visible transmittance but high absorptance over the solar infrared spectrum. To protect the interior of the building from the heat of this absorbed radiation, additional glazings, gas spaces, and cold-climate or low-solar-gain, low-e coatings are added.

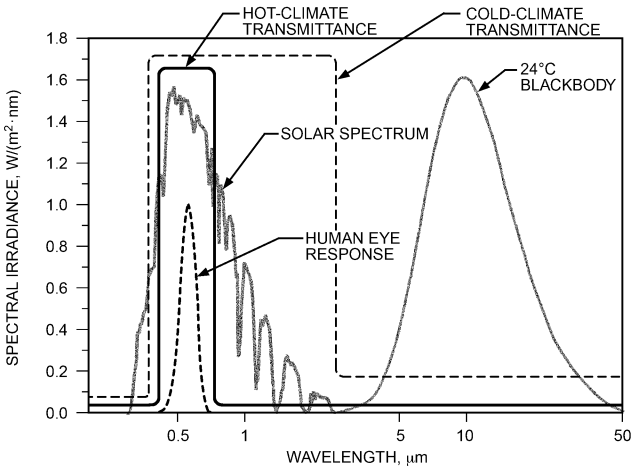

Fig. 14 Demonstration of Two Spectrally Selective Glazing Concepts, Showing Ideal Spectral Transmittances for Glazings Intended for Hot and Cold Climates

By this means, radiation, conduction, and convection of heat from the hot outer pane to the interior ones and to the interior of the building are reduced because of the coating, the gas space, and the additional panes. Such a glazing system for hot climates is insulated primarily *not* to protect the building from conductive heat losses in winter but to protect the interior from solar radiant heat absorbed by the hot outer pane in summer. Many manufacturers offer this kind of nonreflecting, spectrally selective glazing system for commercial and residential buildings having large cooling loads. Figure 14 shows that glazings intended for hot climates should have (1) high transmittance over the visible portion of the spectrum to let daylight in for both illumination and view and (2) low transmittance over all other portions of the spectrum to reduce solar heat gain. In contrast, glazings intended for very cold climates should have high transmittance over the whole solar spectrum, from 0.38 to over 3.5 µm, for maximum admission of solar radiant heat gain and light. In addition, glazings for cold climates should have low transmittance over the long-wavelength portion of the spectrum to block radiant heat emitted by the relatively warm indoor surfaces of buildings, preventing its escape to the outdoors.

Extreme spectral selectivity in glazing systems in the visible portion of the spectrum can produce an unwanted color shift in transmitted light. The color of transmitted light and its color-rendering properties should be considered in the design.

When discussing spectral behavior of fenestration, it is important to understand the relationship between the solar spectrum and the resulting broadband solar-optical properties of glazing systems. A brief introduction is provided here.

Calculation of a glazing system's SHGC (see the section on Solar Heat Gain Coefficient) requires calculating broadband solar transmittance and absorptance. It is influenced by the solar spectrum and the spectral selectivity achieved through the combination of coatings and substrates that make up the glazing system. These two glazing attributes contribute strongly to spectral variations displayed by glazing systems.

To understand any spectral selectivity associated with a glazing layer, it is also necessary to have a good understanding of the spectral distribution of solar radiation. Typically, this is known as a **solar spectrum** or **weighting function,** whose wavelengths range from 300 to 2500 nm. Although there is energy at thermal wavelengths much longer than 2500 nm, glass and polymer layers are opaque to such wavelengths. Of available solar energy, the **direct normal irradiance (DNI)** exhibits the strongest intensity.

Accurate representation of the solar spectrum is essential to calculate broadband solar-optical properties of glazings, which in turn are used to calculate SHGC. It can also be used to compare the solar control characteristics of different glazing layers. Gueymard and Kambezidis (2004) reviewed ways to mathematically describe the atmospheric processes of scattering and absorption, to better consider the effect of atmospheric attenuation of extraterrestrial solar irradiation. This enables more realistic modeling of the DNI spectrum.

Over the past decade, better understanding of atmospheric phenomena that govern the attenuation of extraterrestrial solar radiation has led to updates of reference solar spectra. Because high-quality observational data have become more readily available, many aspects of the scattering and absorption process can now be modeled with increasing confidence. Reference spectra range from the original ASTM *Standard* E891-1989 (RA 1992) spectrum as referred to in the WINDOW4 documentation (Finlayson et al. 1993), through

Licensed for single user. © 2021 ASHRAE, Inc.

the use of ISO *Standard* 9845 as discussed in Rubin et al. (1998) and finally ASTM *Standard* G173-2003 (RA 2008) in the latest NFRC (2014c) *Technical Document* 300-2014.

Note that the solar spectrum referenced by NFRC *Technical Document* 300 (2014c) is identical to that used by the LBNL (2016) WINDOW program for NFRC certification purposes. At present, the DNI spectrum is used to calculate both broadband transmittance and reflectance.

Increased availability of high-quality observational data means it is now possible to develop mathematical models of the attenuation of solar radiation caused by scattering and absorption by aerosols and gases in the atmosphere. Several updates of the solar spectra have been published as a result of better consideration of atmospheric phenomena that govern the attenuation of extraterrestrial solar radiation.

ASTM *Standards* G173 and G197 are examples of recent standards based on version 2.9.2 of the Simple Model of the Atmospheric Radiative Transfer of Sunshine (SMARTS) atmospheric transmission code for the photovoltaic industry (Gueymard and Kambezidis 2004). *Standards* G173 and G197 use angles of tilt (from the horizontal) of 37 and 20°, respectively, which are different from those used in earlier standards such as ASTM *Standard* E891 and ISO *Standard* 9845.

Standards G173 and G197 are regarded as superior solar spectra because of their ability to consider more atmospheric interactions. They have better resolution (2002 wavelengths of information) than older standards (120 wavelengths).

Development and review of newly created solar spectra are ongoing, but there has not yet been a thorough analysis on the influence played by different spectra on the calculated broadband solar transmittance and reflectance. It has been found that some glazing systems (Gueymard and Kambezidis 2004; Lyons et al. 2010), especially those that exhibit strong spectral selectivity, are more sensitive to the choice of solar spectrum compared with glazings having less selective behavior (Gueymard and du Pont 2009). In addition, there has not been any clear guidance on how trapezoidal integration deals with improved resolutions introduced through the newer *Standards* G173 and G197 spectra (Finlayson et al. 1993; ISO *Standard* 15099; Rubin et al. 1998). Most spectral measurements for coated and monolithic glazing layers only have 111 and 441 records respectively, as required by the NFRC.

4.2 SOLAR HEAT GAIN COEFFICIENT

The concept of the solar heat gain coefficient is best shown for the case of a single glass pane in direct sunlight. If $E_D = E_{DN}\cos\theta$ is the direct solar irradiance incident on the glass, with T the solar transmittance, $\mathcal{A}$ the solar absorptance, and N the **inward-flowing fraction** of the absorbed radiation, then the total solar gain (per unit area) q_b that enters the space because of incident solar radiation is

$$q_b = E_D(T + N\mathcal{A}) \tag{8}$$

in units of energy flux per unit area, W/m^2.

The inward-flowing fraction is thermal in origin; it depends on heat transfer properties of the assembly rather than on its optical properties. Absorbed solar radiation, including ultraviolet, visible, and infrared radiation from the sun and sky, is turned into heat inside the absorbing material. In fenestration, the glazing system temperature rises as a result to some approximately equilibrium value at which energy gains from absorbed radiation are balanced by equal losses. Absorbed solar radiation is dissipated through conduction, convection, and radiation. Some heat leaves the building, and the remainder goes indoors, adding to the directly transmitted solar radiation. The magnitude of the inward-flowing fraction depends on the nature of the air boundary layers adjacent to both sides of the glazing, including any gas between the panes of a multiple-pane glazing system (N_i is often used to distinguish the inward-flowing fraction from the outward-flowing fraction, N_o. However, because only the inward-flowing fraction is used here, the subscript i is dropped for clarity).

The quantity in parenthesis in Equation (8) is called the **solar heat gain coefficient (SHGC)**, also known as ***g*-value** or **total solar energy transmittance** in Europe. The total solar gain power per unit area (from direct beam radiation) can therefore be computed using the following equation:

$$q_b = E_D\text{SHGC} \tag{9}$$

The SHGC is needed to determine the solar heat gain through a fenestration's glazing system, and should be included along with U-factor and other instantaneous performance properties in any manufacturer's description of a fenestration's energy performance.

Calculation of Solar Heat Gain Coefficient

Because the optical properties $\mathcal{A}$ and T vary with the angle of incidence and wavelength, the solar heat gain coefficient is also a function of these variables. In the most general way, the solar heat gain power per unit area $q(\theta)$ and the solar heat gain coefficient SHGC(θ,λ) are defined as

$$\begin{aligned} q(\theta) &= \int_\lambda E_D(\lambda)[T(\theta,\lambda) + N\text{A}(\theta,\lambda)]d\lambda \\ &= \int_\lambda E_D(\lambda)\text{SHGC}(\theta,\lambda)d\lambda \end{aligned} \tag{10}$$

where

$E_D(\lambda)$ = incident solar spectral irradiance
$T(\theta, \lambda)$ = spectral transmittance of glazing system
$\mathcal{A}(\theta, \lambda)$ = total spectral absorptance of glazing system

Here, the angle- and wavelength-dependent solar heat gain coefficient is given by

$$\text{SHGC}(\theta,\lambda) = T(\theta,\lambda) + N\mathcal{A}(\theta,\lambda) \tag{11}$$

Combined with Equation (6), this becomes the wavelength-averaged solar heat gain coefficient:

$$\text{SHGC}(\theta) = \frac{\int_{\lambda_{min}}^{\lambda_{max}} E_D(\lambda)[T(\theta,\lambda) + N(\lambda)\text{A}(\theta,\lambda)]d\lambda}{\int_{\lambda_{min}}^{\lambda_{max}} E_D(\lambda)d\lambda} \tag{12}$$

Equations (10) to (12) indicate the preferred way of determining the solar gain of glazing systems and calculating the solar heat gain coefficient. Computer programs such as LBNL (2016) WINDOW are available to assist in the calculation. In WINDOW, the overall system optical properties at a given incident angle are calculated for each wavelength and the results averaged following Equation (12). The ASTM *Standard* G173 spectrum for direct irradiance is generally used in the averaging. The wavelength-averaged properties (at a given incident angle) can then be used in Equation (9). This approach has been adopted by the National Fenestration Rating Council in NFRC (2014d) *Technical Document* 200 for rating, certifying, and labeling fenestration for energy performance and by the Canadian Standards Association (CSA *Standard* A440.2). The method is valid for strongly spectrally selective (as well as nonselective) glazing systems.

When a glazing system is not strongly spectrally selective, the solar-weighted spectral broadband values of the optical properties can be used, and the integral over wavelength shown in Equations (10) and (12) is not needed. In this case, each glazing layer has its own individual inward-flowing fraction of the absorbed radiation for that layer. With the glazings numbered from the outdoors inward, and k the glazing index, the SHGC is given by

Licensed for single user. © 2021 ASHRAE, Inc.

$$\mathrm{SHGC}(\theta) = T^f(\theta) + \sum_{k=1}^{L} N_k \mathrm{A}_k^f(\theta) \quad (13)$$

where

T^f = front transmittance of glazing system
L = number of glazing layers
$\mathcal{A}_k^f$ = absorptance of layer k as part of the composite L-layer system (Finlayson et al 1993; Rubin et al. 1998). This is *different* from the individual, stand-alone absorptance of layer k.
N_k = inward-flowing fraction for layer k

The inward-flowing fractions can be calculated from simplified heat transfer models, using the following equation:

$$N_k = U\sum_{j=k}^{1} R_{j-1,j} \quad (14)$$

where

$\sum R_{j-1,j}$ = sum of resistances from exterior air node up to center of kth glazing layer

Thus, the inward-flowing fraction of layer k is essentially the U-factor of the fenestration times the thermal resistance from the center of the kth layer to the outdoors. In more complicated multilayer glazing systems, it is advisable to perform a detailed heat transfer analysis of the system to determine the values of N_k, because the effective heat transfer coefficients and U depend (weakly) on the glazing layer temperatures and other environmental conditions [e.g., Finlayson et al. (1993), LBNL (2016), Wright (1995a)].

Diffuse Radiation

For incident diffuse radiation, the hemispherical average solar heat gain coefficient must be used. This may be calculated by combining Equation (12) with Equation (7) as follows:

$$\langle \mathrm{SHGC}(\theta)\rangle_D = \frac{\int\int_{hem} \mathrm{SHGC}(\theta)\cos\theta d\varpi}{\int\int_{hem} \cos\theta d\varpi} = 2\int_0^{\pi/2} \mathrm{SHGC}(\theta)\cos\theta d\theta \quad (15)$$

Equivalently, T and $\mathcal{A}$ in Equation (13) can be hemispherically averaged using Equation (7) so that

$$\langle \mathrm{SHGC}\rangle_D = \langle T^f\rangle_D + \sum_{k=1}^{L} N_k \langle \mathrm{A}_k^f\rangle_D \quad (16)$$

In any case, N_k is unaffected in averaging, because it does not depend on incident angle or wavelength. In contrast, T and $\mathcal{A}$ do depend on wavelength. The spectral distribution of diffuse light is notably different from that of direct radiation. However, under usual clear-sky conditions, the fractional amount of diffuse radiation is relatively low compared to that of its direct counterpart, so that the error introduced by neglecting this difference is low in general.

Solar Gain Through Frame and Other Opaque Elements

Figure 15 shows the mechanisms by which fenestration provides solar gain. It is assumed that all of the directly transmitted solar radiation is absorbed at indoor surfaces, where it is converted to heat. Solar gain also enters a building through opaque elements such as the frame and any mullion or dividers that are part of the fenestration system, because part of the solar energy absorbed at the surfaces of these elements is redirected to the indoor side by heat transfer.

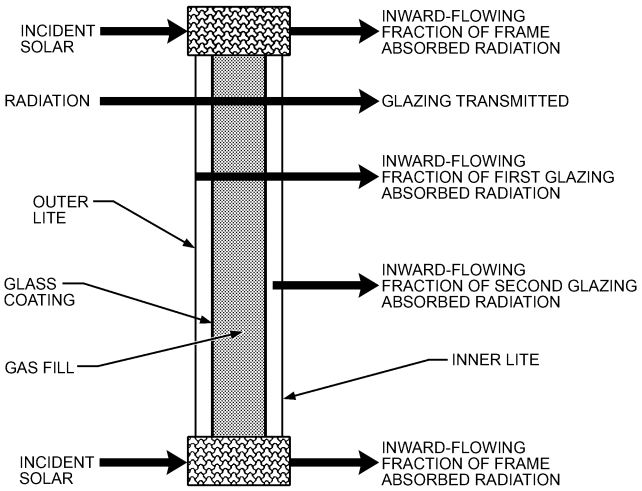

Fig. 15 Components of Solar Radiant Heat Gain with Double-Pane Fenestration, Including Both Frame and Glazing Contributions

The solar heat gain coefficient of the fenestration system can be calculated while accounting for solar gain through the opaque elements by area-weighting the solar heat gain coefficients of the glazing, frame, and M divider elements. Thus,

$$\mathrm{SHGC} = \frac{\mathrm{SHGC}_g A_g + \mathrm{SHGC}_f A_f + \sum_{i=1}^{M} A_i \mathrm{SHGC}_i}{A_g + A_f + \sum_{i=1}^{M} A_i} \quad (17)$$

where SHGC_g, SHGC_f, and SHGC_i are the solar heat gain coefficients of the glazed area, frame, and ith divider, respectively. A_g, A_f, and A_i are the corresponding projected areas.

In some cases, it is useful to have an overall SHGC for the opaque elements only, which is defined by

$$\mathrm{SHGC}_{op} = \frac{\mathrm{SHGC}_f A_f + \sum_{i=1}^{M} A_i \mathrm{SHGC}_i}{A_{op}} \quad (18)$$

where

$$A_{op} = A_f + \sum_{i=1}^{M} A_i$$

SHGC_f can be estimated (ISO *Standard* 15099:2003; Wright 1995b) using

$$\mathrm{SHGC}_f = \alpha_f^s \left(\frac{U_f}{h_f}\right)\left(\frac{A_f}{A_{surf}}\right) \quad (19)$$

where α_f^s is the solar absorptance of the outdoor surface of the frame, U_f is the frame U-factor, and h_f is the heat transfer coefficient (radiative plus convective) between the frame and the outdoor environment. The projected-to-surface area ratio (A_f/A_{surf}) corrects for the fact that U_f is based on projected area A_f, whereas h_f is based on the exposed outdoor frame surface area A_{surf}. SHGC_i can be calculated in the same way:

$$\mathrm{SHGC}_i = \alpha_i^s \left(\frac{U_i}{h_i}\right)\left(\frac{A_i}{A_{surf,i}}\right) \quad (20)$$

Licensed for single user. © 2021 ASHRAE, Inc.

The outdoor-side heat transfer coefficients h_f and h_i can be estimated using

$$h_f \text{ or } h_i = h_{co} + 4\sigma e_f t_{out}^3 \quad (21)$$

where h_{co} is the convective heat transfer coefficient between the frame (or divider) surface and the outdoor environment, e_f is the emissivity (long-wave) of the outdoor frame (or divider) surface, t_{out} is the outdoor temperature, and σ is the Stefan-Boltzmann constant.

Solar Heat Gain Coefficient, Visible Transmittance, and Spectrally Averaged Solar-Optical Property Values

Table 10 lists visible transmittance, solar transmittance, front and back reflectance, and solar heat gain coefficients for common glazing and window systems. The ID number for each entry in Table 10 refers to an ID number in Table 4, and the window systems therefore include windows with aluminum or metal frames and windows with other frames that have a lower conductivity (e.g., thermally broken aluminum, wood, vinyl, and fiberglass). As can be seen in Table 10, total window solar heat gain coefficient varies with type of operator, size of fenestration product, and type of frame.

The glazing T_v, T_{sol}, R^f, R^b, and SHGC values have been calculated using manufacturers' spectral data following methods described in Finlayson and Arasteh (1993) and Wright (1995b), and using the 1.5 air mass spectrum found in ASTM *Standard* G173. Glazing values are given for 3 and 6 mm glass and vary with glass thickness and manufacturer. Values shown are averages and may vary by ±0.05. It is recommended that actual values be determined using detailed spectral data from NFRC (2014b). The front reflectance is that of the unit to the outdoors, and the back reflectance is that to the room side.

Visible transmittances are provided in Table 10 for center-glazing values at normal incidence and for total window values at normal incidence. A rule of thumb is to select a glazing unit whose visible transmittance is 1.5 to 2.0 times greater than its solar heat gain coefficient, especially if daylighting strategies will be used in the building. For maximum light with minimum solar gain, some fenestration products have visible transmittances 2.5 times their SHGCs. For energy calculations on a daylit building, visible transmittance for the entire window should be used. The visible transmittance of a window can be calculated by multiplying the fraction of glazing area by the center-glazing visible transmittance.

Solar heat gain coefficients are provided for center-glazing and total window values. Center-glazing solar heat gain coefficients are given at normal incidence (0°) and at 40°, 50°, 60°, 70°, and 80° incidence angles. For angles other than those listed, straight-line interpolation can be used between the two closest angles for which values are shown. Total window solar heat gain coefficients assume normal incidence. The operable and fixed window sizes in Table 4 were used. To calculate the frame area, frame heights shown in Figure 4 for aluminum and aluminum-clad wood/wood/vinyl were used. The frame area for aluminum windows is 11% for operable size, and 10% for fixed. The frame area for other frames is 20% for the operable size and 12% for fixed. The ratio of projected frame dimension (PFD) to frame surface area is assumed to be 1.0, based on Wright (1995b). In reality, for most frames this ratio is in the range 0.7 to 0.9, because frames cannot simultaneously be flush with both outdoor and indoor glass surfaces. The PFD is defined by the sight line, which is the intersection of the opaque frame (which could be indoors or outdoors) and the vision area.

Frame solar heat gain coefficients used to determine the total window solar heat gain coefficients are calculated according to the section on Solar Gain Through Frame and Other Opaque Elements. Frame U-factors are taken from Table 1. Frame absorptance is assumed to be 0.5 (this is the default NFRC value for commercial frames; however, note that NFRC procedures stipulate 0.3 for residential frames). The outdoor convective film coefficient is 15 W/(m^2·K), corresponding to a wind speed of 2.8 m/s. For the aluminum window, the frame solar heat gain coefficient is 0.14 for the operable window and 0.11 for the fixed. For the other frames, the frame solar heat gain coefficient varies between 0.02 and 0.07 for the various lower-conductivity frame types. A frame solar heat gain coefficient of 0.04 is used for the operable window, and 0.03 for the fixed. These values correspond directly to the aluminum-clad wood/reinforced vinyl frames.

Solar transmittances and front and back reflectances are also center-glazing values and are given at normal incidence (0°) and at 40°, 50°, 60°, 70°, and 80° incidence angles. The effective inward-flowing fraction of absorbed radiation for the entire system (not layer-specific values) can be determined from Equation (9) by inserting the solar transmittance and corresponding SHGC.

Example 5. Estimate the overall visible light transmittance for an operable wood casement window with clear, uncoated 6 mm double glazing. The operable window has 27% frame area with a wood frame.

Solution: The center-glazing visible light transmittance is 0.78 (see Table 10, glazing ID = 5b, first column). The overall visible light transmittance is

$$T_v = 0.27(0) + 0.73(0.78) = 0.57$$

Airflow Windows

If properly managed, airflow between panes of a double-glazed window can improve fenestration performance. In normal use, a venetian blind is located between the glazing layers. Ventilation air from the room enters the double-glazed cavity, flows over the blind, and can be exhausted from the building or returned through the ducts to the central HVAC system.

These systems can control window heat transfer under many different operating conditions. During sunny winter days, the blind acts as a solar air collector; heat removed by the moving air can be used elsewhere in the building. Furthermore, the window acts as a heat exchanger when sunlit so that the indoor glazing temperature nearly equals the room air temperature and improves thermal comfort (also see the section on Occupant Comfort and Acceptance). In the summer, the window can have a very low solar heat gain coefficient if the blinds are appropriately placed, because the majority of solar gains are removed from the window.

Brandle and Boehm (1982) and Sodergren and Bostrom (1971) give details on airflow windows.

Skylights

Skylight solar heat gain strongly depends on the configuration of the space below or adjacent to (i.e., in sloped applications) the skylight formed by the skylight curb and any associated light well.

Five aspects must be considered: (1) transmittance and absorptance of the skylight unit, (2) transmitted solar flux that reaches the aperture of the light well, (3) whether that aperture is covered by a diffuser, (4) transmitted solar flux that strikes the walls of the light well, and (5) reflectance of the walls of the light well. Data for flat skylights, which may be considered as sloped glazings, are found in Tables 4 and 11.

The following categories of skylights all admit daylight from the roof plane but differ markedly in their design.

Domed Skylights. Solar and total heat gains for domed skylights can be determined by the same procedure used for windows. Table 11 gives SHGCs for plastic domed skylights at normal incidence (Shutrum and Ozisik 1961). Manufacturers' literature has further details. Given the poorly defined incident angle conditions for domed skylights, it is best to use these values without correction for incident angle, together with the correct (angle-dependent) value of incident solar irradiance. Results should be considered approximate. In the absence of other data, these values may also be used to make estimates for skylights on slanted roofs.

Sources: Laouadi et al. (2003), Schutrum and Ozisik (1961).

Tubular Daylighting Devices (TDDs). Tubular daylighting devices collect and channel daylight (diffuse sky and sunbeam light) from the roof of a building into interior spaces (Figure 16). TDDs are also known as **mirror light pipes** or **tubular skylights**. They are an alternative to conventional skylights and have the advantages of energy savings (small area relative to the amount of useful light they admit), lower solar heat gains, relative ease of installation, and tube lengths (depending on the tube length-to-diameter ratio) of up to 13 m. TDD technologies undergo continuous development to meet the increasing needs for high standards of energy efficiency in buildings and glare-free lighting. The energy-saving potential of TDDs is well recognized (Allen 1997; Carter 2008; Laouadi 2004), and TDDs are encouraged or mandated, particularly in commercial buildings [CEC 2010; see also U.S. Green Building Council's (USGBC) Leadership in Energy and Environmental Design (LEED) program]. A variant known as a hybrid TDD (HTDD) is available from some manufacturers. In an HTDD, more than one material or geometry is present along the length of the tube (e.g., a round tube that transitions to a square ceiling diffuser).

The natural daylight that TDDs deliver is beneficial to the visual comfort, health, and well-being of building occupants (Boyce et al. 2003; Carter and Al-Marwaee 2009). The daylighting performance (light output) of a TDD depends on many location and material parameters, but a typical device can illuminate an area of up to 28 m^2. The area of coverage depends on the height of the ceiling: the higher the ceiling, the more widely the light will be uniformly distributed.

TDD Components. TDDs typically consist of (1) a collector on the roof to gather sunbeams and diffuse sky light, (2) a hollow pipe guide in the plenum/attic space to channel light downwards, and (3) a light diffuser at ceiling level to spread light indoors (see Figure 16).

The **collector** is usually a single- or multilayer transparent glass or plastic dome projecting above the plane of the roof. It may also include passive or active geometries (e.g., static or tracking reflectors) or some optical devices (e.g., prisms, diffusing elements) to enhance the device's lighting output, especially at low sun altitude angles (Laouadi 2013).

Straight **guides** (tubes) are common, but nonlinear light guides with bent sections (Figure 16) are sometimes needed to suit the geometry of a building. The guide can be rigid or flexible, and is typically made from an aluminum sheet with highly reflective interior coatings, which are sometimes spectrally selective. This measure reduces solar heat transmission while preserving light transmission. Coating materials with a reflectivity exceeding 99% are commercially available. Vertical pipes without bends are more efficient than bent guides for low incidence angles (<60°; e.g., summer noon), and less efficient for higher incidence angles (e.g., winter noon) (Laouadi et al. 2013a).

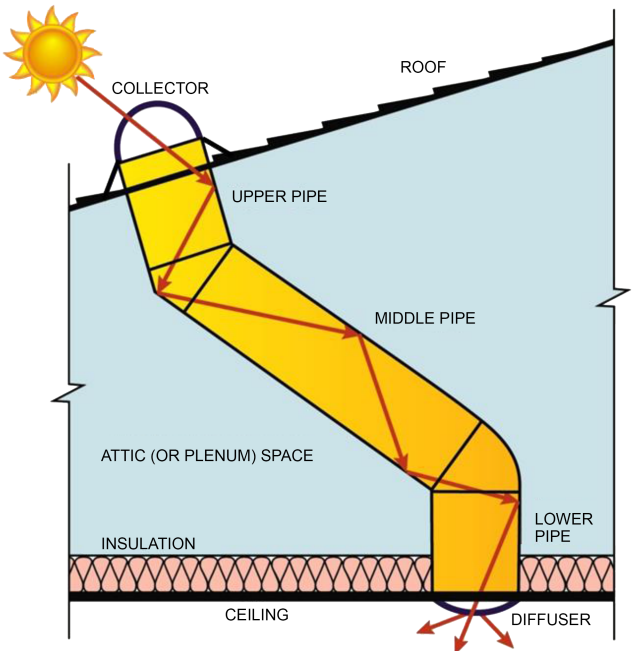

Fig. 16 Generalized Tubular Daylighting Device
(NRCC 2011)

Diffusers in the ceiling plane of TDDs are usually hemispherical or flat with single- or multilayer glass or poly(methyl methacrylate (PMMA, also known as acrylic) or polycarbonate. Diffusers typically use one of three types of glazing: prismatic, diffusing, or lensed. **Prismatic** glazing consists of arrays or layers of micro replicated shapes (conical prisms, ridges, wedges, etc.), which reflect, refract, and redirect the incoming light based on the angle of incidence. Typical prismatic diffusers are made of acrylic or polycarbonate sheets with conical prisms. **Diffusing** glazing consists of very fine particles, pigments, or films applied to clear glass or plastic sheets to make the glazing look opal (white). The scattering properties depend on the refractive index and the size of the microstructures used. **Lensed** glazing is comprised of arrays of diverging lenses (e.g., Fresnel lenses) that are very thin so that little light is lost by absorption.

Performance Metrics. Various theoretical and empirical models have been developed to predict the daylighting performance of TDDs [e.g., CIE (2006), Zhang and Muneer (2000)]. ASHRAE research project RP-1415 developed and validated models for the prediction of the optical and thermal performance of complex TDDs (Laouadi et al. 2013b, 2013c, 2013d). Several metrics were proposed, including

- **Visible transmittance (VT):** calculated or measured at a standard incidence angle, or averaged over a predetermined number of incidence angles. Angle of incidence is the angle between the entering ray and the axis of the upper tube section.
- **Normalized intensity distribution:** an index that treats TDDs as lighting luminaire systems. TDD intensity distribution is important for lighting energy calculation and spatial arrangement of TDDs.

Licensed for single user. © 2021 ASHRAE, Inc.

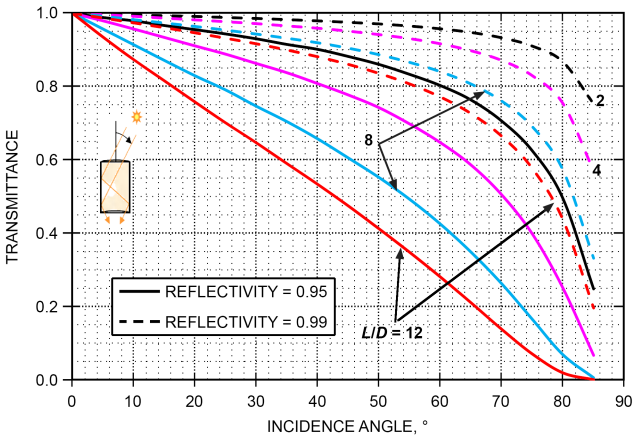

Fig. 17 Transmittance of Straight Tube (Light Pipe) as Function of Reflectivity and Aspect Ratio (Length/Diameter)

- **Daylighting area coverage (DAC):** portion of the work plane surface area under a daylight illuminance equal or greater than the recommended task illuminance under CIE standard clear sky conditions. DAC is an important parameter for TDD product rating and selection, and spatial arrangement that guarantees capital cost reduction (with minimum number of TDDs).
- **Spacing ratio (SR):** maximum distance between two pairs of TDDs, normalized by the ceiling height of buildings. SR is calculated based on the illuminance uniformity criterion on the work plane surface.
- **Solar heat gain coefficient (SHGC):** normalized solar heat gains penetrating the indoor space through a TDD system when sunbeam light is incident on the TDD pipe aperture at a standard angle.
- **Thermal transmittance (U-factor):** heat loss from a TDD to the outdoors per unit surface area and temperature difference between the indoor and outdoor environments under standard thermal conditions.

Simplified Single-Angle Solar and Visible Analysis. The following simplified equations are presented only as a guide to solar-optical behavior of a TDD. Real-world TDD performance is a function of many location-specific and season-dependent factors (especially solar angle of incidence) which lead to the final, effective SHGC and VT being a somewhat complex weighted average.

For a given input solar ray and angle of incidence, the visible (or solar) transmittance of a TDD is the product of the individual visible (or solar) transmittances of the collecting dome c, the tube t, and the ceiling diffuser d:

$$T_{TDD} = t_c t_t t_d$$

Of the three terms on the right-hand side of the equation, tube transmittance t_t is by far the most sensitive to the incidence angle of the ray (Figure 17) and the presence of any optical element in the collector, which may change the angle of the incident ray. The equation also assumes that multiple interreflections between TDD components make a negligible contribution to the overall system transmittance and throughput of light. This is approximately true for large aspect ratios. The solar heat gain coefficient of the TDD is the sum of the (solar) transmittance plus an indirect, thermal term that is analogous to the inward-flowing fraction of solar heat gain from a general glazing system. The fraction of original, outdoor solar power incident on the diffuser is

$$I_d/I_s = t_c t_t$$

Table 12 Performance Characteristics of Typical TDDs

Glazing of Collector/ Diffuser	Single/ Single Layer	Double/ Double Layer	Double/ Single Layer	Single/ Double Layer	Single/ Triple Layer
Visible transmittance*	0.77	0.63	0.72	0.66	0.58
SHGC* (250 mm insulation above ceiling)	0.32	0.24	0.27	0.28	0.24
SHGC* (250 mm insulation under roof)	0.34	0.33	0.32	0.35	0.34
U-factor, W/(m²·K) (250 mm insulation above ceiling)	3.54	2.16	3.53	2.17	1.55
U-factor (250 mm insulation under roof)	7.62	4.70	4.70	7.60	7.58

*VT and SHGC calculated at solar incidence angle of 50° at due south; this angle is close to annual averaged incidence angle (48.84°) of NFRC *Standard* 203-2014.

where I_s and I_d are the solar fluxes (W/m²) incident on the collector dome and diffuser respectively.

The fraction of incident solar radiation energy absorbed in the diffuser is α_d of which approximately half is transferred downward by convection and radiation into the building. The other half is transferred upward to the column of air in the tube. The fraction of this power that is transferred inward is equal to $0.5t_c t_t \alpha_d$.

Thus the solar heat gain coefficient of the TDD system, and where all optical parameters are determined for the solar spectrum, is approximately

$$SHGC_{TDD} = T_{TDD} + 0.5t_c t_t \alpha_d = t_c t_t (t_d + 0.5\alpha_d)$$

The National Fenestration Rating Council (NFRC) sets the model sizes and environmental conditions for the product rating of TDDs. At the time of writing, NFRC ratings are based on physical testing only, after a former NFRC simulation procedure for U-factor of TDDs was retired in 2012. TDD ratings for U-factor follow NFRC (2014a) *Technical Document* 100. Ratings for SHGC follow NFRC (2014e) *Technical Document* 201-2014, whereas ratings for VT follow NFRC (2014f) *Technical Document* 203-2014, which in turn references ASTM *Standard* E1175-87 (RA 2015).

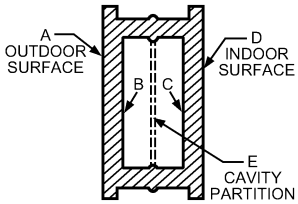

Table 12 shows the computed optical and thermal characteristics of a typical TDD made up of a 3 mm PMMA collector and a 3 mm polycarbonate diffuser with an NFRC standard-size pipe of 350 mm diameter and aspect ratio of 2.14. The tube reflectivity is 99% and 76% for the visible and solar spectrum, respectively. The NFRC *Technical Document* 100 boundary conditions (NFRC 2014a) are used for the U-factor calculation. The table shows that, although the number of layers in the collector or diffuser has only a small effect on visible transmittance, as expected it has a significant effect on thermal performance. The table does not show any best arrangement, but provides information that can help a designer select an arrangement that best suits a particular application in residential or commercial buildings.

Practical Guidelines. When selecting TDDs, specifiers should consider the following:

- **Visible transmittance:** products with the highest visible transmittance should be selected for daylighting.
- **Solar heat gain coefficient:** ideally, for heating-dominated climates, TDDs would have moderate to high SHGC. However, most available TDDs have medium to low SHGC (<0.40) by design, because ENERGY STAR (www.energystar.gov) requires SHGC ≤ 0.40 except in the northern U.S. climate zone. Some indicative, real-world solar heat gain coefficients are given in Table 12. All exceed the minimum performance defined by ENERGY STAR (i.e., rated SHGC is lower than the ENERGY STAR upper limit).

Table 13 Solar Heat Gain Coefficients for Standard Hollow Glass Block Wall Panels

Type of Glass Block[a]	Description of Glass Block	Solar Heat Gain Coefficient	
		In Sun	In Shade[b]
Type I	Glass colorless or aqua A, D: Smooth B, C: Smooth or wide ribs, or flutes horizontal or vertical, or shallow configuration E: None	0.57	0.35
Type IA	Same as type I except ceramic enamel on A	0.23	0.17
Type II	Same as type I except glass fiber screen partition E	0.38	0.30
Type III	Glass colorless or aqua A, D: Narrow vertical ribs or flutes. B, C: Horizontal light-diffusing prisms, or horizontal light-directing prisms E: Glass fiber screen	0.29	0.23
Type IIIA	Same as type III except E: Glass fiber screen with green ceramic spray coating or glass fiber screen and gray glass or glass fiber screen with light-selecting prisms	0.22	0.16
Type IV	Same as type I except reflective oxide coating on A	0.14	0.10

[a]All values are for 200 by 200 by 100 mm block, set in light-colored mortar. For 300 by 300 by 100 mm block, increase coefficients by 15%, and for 150 by 150 by 100 mm block, reduce coefficients by 15%.

[b]For NE, E, and SE panels in shade, add 50% to values listed for panels in shade.

Licensed for single user. © 2021 ASHRAE, Inc.

- **U-factor:** the lower the U-factor, the better. ENERGY STAR-qualified TDDs must achieve a U-factor of ≤ 1.5 W/(m^2·K) in the northern U.S. climate zone. This is relaxed somewhat as one moves to progressively warmer climates, leading to a threshold of 2.3 W/(m^2·K) in the southern climate zone. Products that are insulated above the ceiling perform considerably better than those with insulation under the roof.
- **Tubular daylighting devices:** TDDs should have multipane ceiling diffusers when insulation is placed at ceiling level (e.g., residential buildings) or multipane collectors when insulation is placed at roof level (e.g., commercial buildings) to reduce thermal losses. In residential applications, a multipane ceiling diffuser is the single most effective measure to reduce the overall U-factor of a TDD. This is because tubes typically penetrate an unconditioned attic zone. In winter, heat loss from tube cavity to attic zone can be severe, and disproportionately large in comparison with the TDD's cross-sectional area, if the ceiling diffuser is only single-glazed.
- **Spacing ratio (SR):** SR relates to the normalized luminous intensity distribution of TDDs. To minimize capital cost (number of TDDs), select TDDs with higher spacing ratios. For ideally diffusing TDDs, SR varies from 1 to 1.5 for illuminance uniformity (minimum to average ratio) of 0.95 to 0.8, respectively.

Installation. Installation methods vary depending on roof type (asphalt shingles, roof tiles, membranes, metallic roofing, etc.). TDD assemblies must be installed to resist air and water infiltration, and damage from wind, hail, and snow load. Manufacturers' instructions provide specific details. Attention to detail is required when the roof is replaced.

Glass Block Walls

Glass block can be used for light transmission through outdoor walls when optical clarity for view is unnecessary. Table 13 describes a variety of glass block patterns and gives solar heat gain coefficients to be applied to solar irradiances so that approximate instantaneous solar heat gains can be calculated (Smith and Pennington 1964). Table 4, footnote 6, provides a representative U-factor for glass block. Note that the U-factor for glass block is poor when compared to double glazing with a low-emissivity coating.

Convection and low-temperature radiative heat gain for all hollow glass block panels fall within a narrow range. Differences in SHGCs are largely the result of differences in transmittance of glass blocks for solar radiation. Solar heat gain coefficients for any particular glass block pattern vary depending on orientation and time of day. The SHGC for western exposures in the morning (shaded) is depressed because of heat storage in the block, whereas the SHGC for eastern exposures in the afternoon (shaded) is elevated as stored heat is dissipated. Time lag effects from heat storage are estimated by using solar gains and air-to-air temperature differences for one hour earlier than the time for which the load calculation is made.

Calorimeter tests of Type 1A glass block showed little difference in solar heat gains between glass block with either black or white ceramic enamel on the exterior of the block. White and black ceramic enamel surfaces represent the two extremes for reflecting or absorbing solar energy; therefore, glass block with enamel surfaces of other colors should have solar heat gain coefficients between these values. Because glass blocks are good examples of strongly angularly selective fenestrations, appropriate caution must be taken.

Plastic Materials for Glazing

Generally, factors outlined for glass apply also to glazing materials such as acrylic, polycarbonate, polystyrene, or other plastic panels. If solar transmittance, absorptance, and reflectance are known, the SHGC can be calculated in the same way as for glass. These properties can be obtained from the manufacturer or be determined by simple laboratory tests. The National Fenestration Rating Council developed standards for testing the optical properties of glazing (NFRC 2014d, 2014g).

In selecting plastic panels for glazing, concerns include possible deterioration from the sun, expansion and contraction because of temperature extremes, and possible damage from abrasion.

4.3 CALCULATION OF SOLAR HEAT GAIN

To calculate solar energy fluxes, first calculate the incident angle θ from the local standard time and the longitude. The direct normal solar irradiance E_{DN}, diffuse sky irradiance E_d, ground-reflected radiation E_r, and total incident irradiance E_t can then be determined. Note that the latter two are assumed to be ideally diffuse radiation. Calculation methods for these parameters are described in Chapter 14.

Solar energy flow through a fenestration may be divided into two parts: opaque (q_{op}) and glazing (q_s) portions. The glazing solar energy flux q_s can be split into that from incident beam radiation

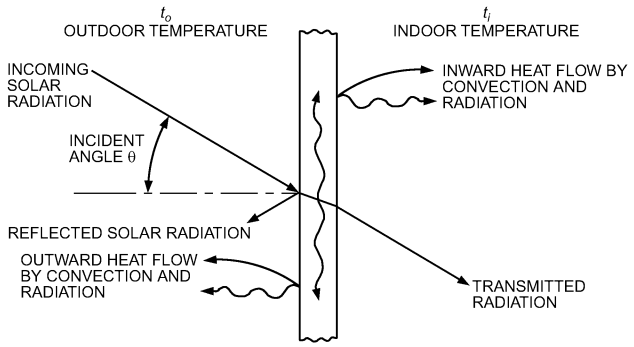

Fig. 18 Instantaneous Heat Balance for Sunlit Glazing Material

(q_b) and incident diffuse radiation (q_d), which includes both diffuse sky radiation and radiation scattered (reflected) from the ground:

$$q_s = q_b + q_d \tag{22}$$

The net heat balance that would occur for a sunlit glazing if there were no diffuse radiation is shown in Figure 18. This net heat balance does not include any of the heat flows resulting from indoor/outdoor temperature differences. The heat balance is pictured as superimposed on the thermal effect. This superposition picture should not be carried too far, however, because the heat flows indicated in Figure 18 as resulting from convection and radiation depend in part on processes that are nonlinear with respect to temperature, so that in reality the two effects cannot be separated. To calculate them, the actual glazing (and other) temperatures are needed, not simply the incremental temperature rise caused by sunlight.

Figure 18 shows that the glazing solar energy flow from beam radiation consists of two parts:

$$q_b = q_{bt} + q_{ba} \tag{23}$$

where

q_{bt} = glazing solar energy flux caused by transmitted incident beam radiation

q_{ba} = glazing solar energy flux caused by inward heat flow of absorbed beam radiation

The glazing solar energy flux caused by incident beam radiation is calculated from

$$q_b = E_{DN} \cos\theta \, \mathrm{SHGC}(\theta) \tag{24}$$

where the beam solar heat gain coefficient is given by Equation (12) or (13). If, instead, the solar radiant and heat fluxes are needed separately, calculate the glazing transmitted solar flux (solar radiation traveling in the incident direction) from

$$q_{bt} = E_{DN} \cos\theta \, T(\theta) \tag{25}$$

and the inward-flowing absorbed solar flux (heat) from

$$q_{ba} = E_{DN} \cos\theta \sum_{k=1}^{L} N_k \mathcal{A}_k^f(\theta) \tag{26}$$

Values of $T(\theta)$ and $\mathcal{A}^f(\theta)$ in these equations can be found in Table 10, and determination of N_k is discussed in the section on Calculation of Solar Heat Gain Coefficient.

For diffuse radiation,

$$q_d = q_{dt} + q_{da} \tag{27}$$

where

q_{dt} = glazing solar energy flux caused by transmitted incident diffuse radiation

q_{da} = glazing solar energy flux caused by inward heat flow of absorbed diffuse radiation

Glazing solar energy flux caused by diffuse incident radiation is calculated from

$$q_d = (E_d + E_r)\langle \mathrm{SHGC} \rangle_D \tag{28}$$

where the hemispherically averaged solar heat gain coefficient is calculated from Equation (15). Solar radiant and heat fluxes can be separately calculated from

$$q_{dt} = (E_d + E_r)\langle T \rangle_D \tag{29}$$

which is diffusely distributed solar radiation (note that effects of finite glazing size and thickness are neglected), and

$$q_{da} = (E_d + E_r) \sum_{k=1}^{L} N_k \langle \mathcal{A}_k^f \rangle_D \tag{30}$$

Opaque Fenestration Elements

The opaque portion solar energy flux is calculated from

$$q_{op} = (E_{DN} \cos\theta + E_d + E_r)\mathrm{SHGC}_{op} \tag{31}$$

where SHGC_{op} is obtained from Equation (18).

Example 6. Calculate the solar energy flux through the glazing system ID 25a given $\theta = 60°$, $E_{DN} = 600$ W/m^2, and $E_d = 150$ W/m^2.

Solution: The solar heat gain coefficients are SHGC(60°) = 0.34, and $\mathrm{SHGC}_D = 0.36$ (see Table 10, glazing ID 25a, 5th and 8th columns).

$$\begin{aligned} q_s &= q_b + q_d \\ &= E_{DN} \cos(60) \mathrm{SHGC}(60) + (E_d + E_r)\langle \mathrm{SHGC} \rangle_D \\ &= (600.0)\cos(60)(0.34) + (150)(0.36) = 156 \text{ W/m}^2 \end{aligned}$$

5. SHADING AND FENESTRATION ATTACHMENTS

5.1 SHADING

The most effective way to reduce the solar load on fenestration is to intercept direct radiation from the sun before it reaches the glazing system. Fenestration products fully shaded from the outdoors reduce solar heat gain by as much as 80%. Fenestration can be shaded by roof overhangs, vertical and horizontal architectural projections, awnings, heavily proportioned outdoor louvers, or a variety of vegetative shades, including trees, hedges, and trellis vines. In all outdoor shading structures, it is necessary to consider the structures' geometry relative to changing sun position to determine the times and quantities of direct sunlight penetration. A detailed discussion of the effectiveness of outdoor shading is given in Ewing and Yellott (1976).

The general effect of shading is to attenuate solar radiation. Some of the beam radiation may reach the fenestration unaffected by the shade, and this is accounted for by the unshaded fraction F_u. Assuming that the shade does not transmit or diffuse solar radiation, the solar heat gain of the fenestration can be approximated by modifying Equation (22):

$$q_s = F_u q_b + q_{d,shaded} \tag{32}$$

Here, the term $q_{d,shaded}$ indicates that a new SHGC must be determined to account for the fact that the shading device restricts the amount of sky-diffuse radiation on the fenestration system. More

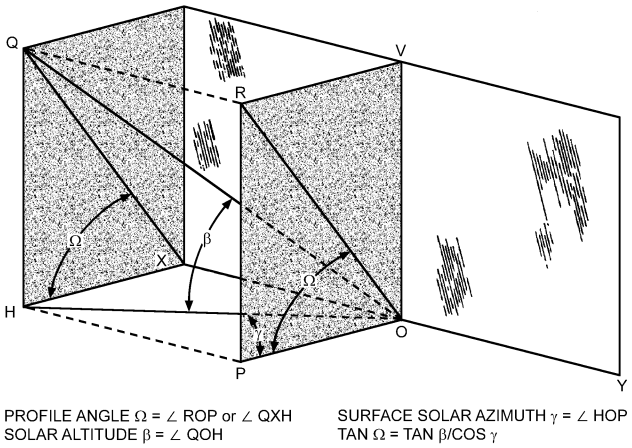

Fig. 19 Profile Angle for South-Facing Horizontal Projections

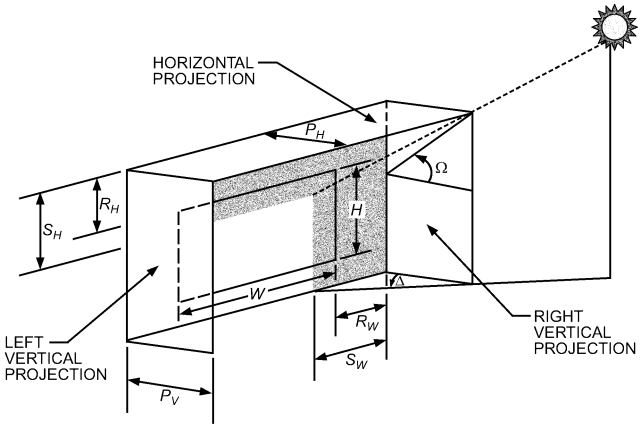

Fig. 20 Vertical and Horizontal Projections and Related Profile Angles for Vertical Surface Containing Fenestration

complex models are required for situations where the shade is partially transmitting and diffusing in nature.

Overhangs and Glazing Unit Recess: Horizontal and Vertical Projections

In the northern hemisphere, horizontal projections can considerably reduce solar heat gain on south, southeast, and southwest exposures during late spring, summer, and early fall. On east and west exposures during the entire year, and on south exposures in winter, the solar altitude is generally so low that, to be effective, horizontal projections must be excessively long. On the other hand, recessing the fenestration deeper back into the wall achieves the same effect as a horizontal projection.

The ability of horizontal projections to intercept the direct component of solar radiation depends on their geometry and the profile or shadow-line angle Ω (Figure 19), defined as the angular difference between a horizontal plane and a plane tilted about a horizontal axis in the plane of the fenestration until it includes the sun. The vertical profile angle Ω can be calculated by

$$\tan \Omega = \tan \beta / \cos \gamma \tag{33}$$

where

β = solar altitude angle
γ = solar azimuth

The shadow width S_W and shadow height S_H (Figure 20) produced by the vertical and horizontal projections (P_V and P_H), respectively, can be calculated using the surface solar azimuth γ and the vertical profile angle Ω determined by Equation (33).

$$S_W = P_V |\tan \gamma| \tag{34}$$

$$S_H = P_H \tan \Omega \tag{35}$$

When the surface solar azimuth γ is greater than 90° and less than 270°, the fenestration product is completely in the shade; thus, $S_W = W + R_w$ and sunlit area $A_{SL} = 0$.

The sunlit (A_{SL}) and shaded (A_{SH}) areas of the fenestration product are variable during the day and can be calculated for each moment using the following relations:

$$A_{SL} = [W - (S_W - R_W)][H - (S_H - R_H)] \tag{36}$$

$$A_{SH} = A - A_{SL} \tag{37}$$

where A is total fenestration product area.

For software-based or multiple calculations, McCluney (1990) describes an algorithm that can be used to calculate the unshaded fraction of a window equipped with overhangs, awnings, or side fins.

Example 7. A window facing 30° south of west (wall azimuth ψ = +60°) in a building at 33.65°N latitude, and 84.42°W longitude is 1841.5 mm wide and 6286.5 mm high. The depth of the horizontal projection is 2438 mm. At 3:00 PM on July 21, it is calculated that the hour angle $H = 15 \times (13.27 - 12) = 19.03°$; and the declination δ = 20.60°.

The solar altitude β is calculated to be:

$$\sin \beta = \cos(33.65) \cos(20.60) \cos(19.03) + \sin(33.65) \sin(20.60)$$

$$\beta = 68.7°$$

The solar azimuth ϕ is

$$\cos \phi = [\sin(68.68) \sin(33.65) - \sin(20.60)]/[\cos(68.68) \cos(33.65)]$$

$$\phi = 57.1°$$

Thus, the wall solar azimuth is γ = 57.1 – 60 = –2.9°.

(a) Find the sunlit and shaded area of the window.

(b) Find the depth of the projections necessary to fully shade the window.

Solution:

(a) Using Equation (34), the width of the vertical projection shadow is

$$S_W = 0 \, |\tan(-2.9)| = 0 \text{ mm}$$

Using Equation (33), the profile angle for the horizontal projection is

$$\tan \Omega = \tan(68.7)/\cos(2.9)$$

$$\Omega = 68.7°$$

Using Equation (35), the height of the horizontal projection shadow is

$$S_H = 96 \tan(68.7) = 6255 \text{ mm}$$

Using Equations (36) and (37), the sunlit and shaded areas of the window are now

$$A_{SL} = [1841.5 - (0 - 0)][6286.5 - (6255 - 0)]/10^6 = 0.058 \text{ m}^2$$

$$A_{SH} = (1841.5 \times 6286.5)/10^6 - 0.058 = 11.519 \text{ m}^2$$

(b) The shadow length necessary to fully shade the given window $S_{H(fs)}$ and $S_{W(fs)}$ from the horizontal and vertical projection are given by (see Figure 20)

$$S_{H(fs)} = 6286.5 + 0 = 6286.5 \text{ mm}$$

$$S_{W(fs)} = 1841.5 + 0 = 1841.5 \text{ mm}$$

Thus, using Equations (34) and (35),

$$P_{H(fs)} = 6286.5 \cot(68.7) = 2453.5 \text{ mm}$$

$$P_{W(fs)} = 1841.5 |\cot(-2.9)| = 36\,351.7 \text{ mm}$$

Licensed for single user. © 2021 ASHRAE, Inc.

For this example, because both horizontal and vertical projections do not need to fully shade the window, a horizontal projection of 2454 mm is satisfactory. Also, to accurately analyze the influence of external projections, an hour-by-hour calculation must be performed over the periods of the year for which shading is desired.

5.2 FENESTRATION ATTACHMENTS

Fenestration attachments generally consist of items that can be used as part of a system to provide solar and daylighting control, as well as privacy, aesthetics, and comfort for building occupants. Attachments also include other devices that, though not intended for solar control, affect the solar and visual performance of the fenestration system. Attachments to the indoor side of fenestration can include horizontal louvers (venetian blinds), vertical louvers, roller shades, insect screens, and drapery. Between glazings of multiglazed fenestration, horizontal louvers and roller shades may be incorporated. On the outdoor side, insect screens can be added, as well as horizontal louvers in the plane of the fenestration.

Fenestrations with shading devices have a degree of thermal and optical complexity far greater than that of unshaded fenestrations, and are referred to as **complex fenestration**.

In unshaded fenestration, individual glazing layers can only communicate thermally with adjacent layers. This is not the case for complex fenestration. A fenestration layer such as a screen or louvered blind is not sealed, and allows convective heat transfer between nonadjacent layers. Similarly, shading layers are inherently diathermanous (i.e., they transmit both long- and short-wave radiation). Radiative heat transfer, therefore, can also occur between nonadjacent layers. For example, for a window with indoor venetian blinds, heat transfer occurs between the indoor glass and the blind, the indoor glass and the room, and between the blind and the room. Therefore, methods described previously for determining the U-factor and inward-flowing fractions of fenestration systems cannot be applied to complex fenestration (Collins and Wright 2006; Wright 2008).

Also, complex fenestration can have a **nonspecular optical element.** This is an element for which light (or short-wave infrared radiation) incident on the element from a single spatial direction does not emerge traveling in a single transmitted direction and/or a single reflected direction. Examples of nonspecular elements are shades, drapes, blinds, honeycombs, figured glass, ground glass, and other diffusers, lenses, prisms, and holographic glazings.

Two methods have been developed that allow the analysis of complex fenestration. The first method was proposed by Klems (1994a, 1994b, 2001), and relies on measurement of the bidirectional transmittance and reflectance of each glazing layer, and on calorimetrically determined values of inward flowing fraction, as input to a matrix calculation. It is a physically based and highly accurate approach that is also computationally and experimentally intensive. For details of this approach, see Chapter 31 of the 2005 *ASHRAE Handbook—Fundamentals*. The second method, developed through ASHRAE-sponsored research (Wright et al. 2008), is an empirically based approach that uses readily available information about the system geometry and material properties, and is designed to fit into established fenestration analysis methodology. The methodology has been shown to accurately predict complex fenestration performance from easily obtained data regarding shade geometry and material.

In contrast to these two methods, a simplified approach is presented in the following section for calculating the approximate SHGC for a selection of the more common shading elements and glazing systems.

Simplified Methodology

Considering only the approximate total heat flux through the fenestration, measurements made on a fenestration under one set of conditions can often be extrapolated to other fenestrations and conditions to give an adequate answer. In this case, heat flux through the center-glass region is represented by

$$q = E_{DN}\cos(\theta)\mathrm{SHGC}(\theta)\mathrm{IAC}(\theta,\Omega) + (E_d + E_r)\langle\mathrm{SHGC}\rangle_D\mathrm{IAC}_D \quad (38)$$

where the solar heat gain coefficients are for the center-glass region of an unshaded glazing, and may be calculated using methods described previously, or obtained from Table 10. The **indoor solar attenuation coefficient (IAC)** represents the fraction of heat flow that enters the room, some energy having been excluded by the shading. Depending on the type of shade, it may vary angularly and with shade type and geometry. The IAC is defined as

$$\mathrm{IAC}(\theta,\Omega) = \frac{\mathrm{SHGC}(\theta,\Omega)_{cg,\,shaded}}{\mathrm{SHGC}(\theta)_{cg}}$$
$$\mathrm{IAC}_D = \frac{\langle\mathrm{SHGC}\rangle_{D,\,cg,\,shaded}}{\langle\mathrm{SHGC}\rangle_{D,\,cg}} \quad (39)$$

where Ω is either the horizontal or vertical profile angle.

IAC values presented in the following sections have been determined using the ASHWAT models (Wright et al. 2008), which have been validated, with calorimetric results showing prediction of fenestration performance to within 5% (Figure 21).

Because shading layers generally have a small effect on the U-factor of complex fenestration systems (Wright et al. 2008), in this simplified analysis, the effects of shading devices on U-factor are ignored. System U-factor is assumed to be similar to that of the same glazing (minus the shade) and can be determined from Table 4.

Note that this simplified approach applies only to the SHGC of the center-glass region of the fenestration product. Results from this analysis must be combined with the methods provided in the Solar Heat Gain Coefficient and Solar Heat Gain sections.

Slat-Type Sunshades

Slat-type sunshades consist of horizontal or vertically oriented louvers in located in the plane of the fenestration. They can be installed on the outdoor and indoor side of the fenestration, or between glazings in a multilayered glazing system. The transmitted solar radiation may consist of straight-through, transmitted diffuse, and reflected-through components.

The geometry considered is shown in Figure 22, with slat width w, slat crown c, slat spacing s, and slat angle ϕ. The ratios of w/s and w/c are assumed constant at 1.2 and 16 respectively, which are representative of many commercially available products. The profile angle Ω can represent either the vertical profile Ω_V or the horizontal profile Ω_H. The vertical profile angle is used for horizontal louvered shades, and is calculated using Equation (33). The horizontal profile angle is used for vertical louvered shades and is equal to the wall surface solar azimuth γ.

Tables 14A to 14G presents IAC values at profile angles of 0 and 60° for various glazing and shade combinations. IAC varies with profile angle where the profile angle can be the vertical profile (for horizontal louvers) or horizontal profile (for vertical louvers). The variation of IAC with profile angle can be determined from

$$\mathrm{IAC}(\theta,\Omega) = \mathrm{IAC}_0 + \mathrm{IAC}_x \times \min(1.2\Omega, 60)/60 \quad (40)$$

Barnaby et al. (2009), Collins et al. (2008), Huang et al. (2006), Kotey et al. (2009a), and Wright et al. (2008) contain more

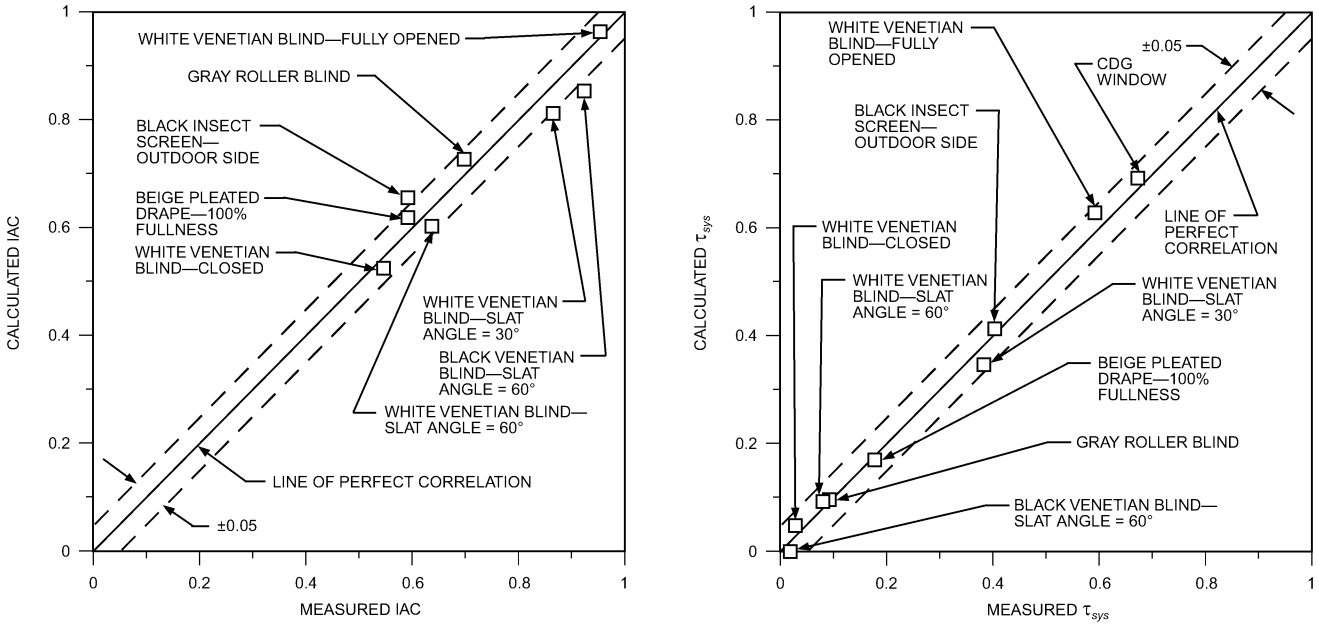

Fig. 21 Comparison of IAC and Solar Transmission Values from ASHWAT Model Versus Measurements
(normal incidence; various shading layers attached to conventional double-glazed window)
(Wright et al. 2009b)

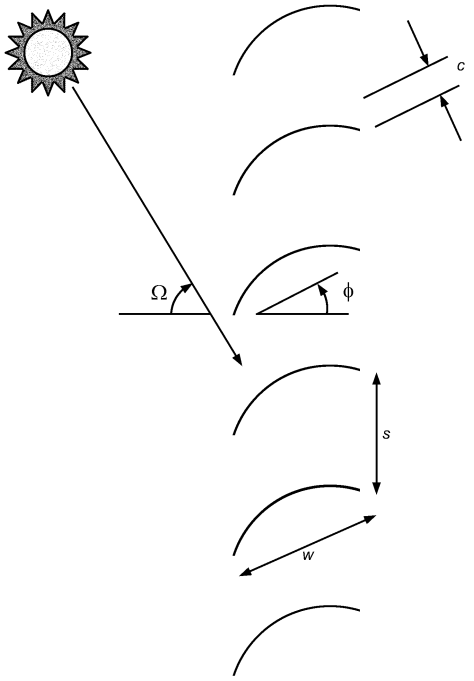

Fig. 22 Geometry of Slat-Type Sunshades

comprehensive discussions of models used to determine IACs of louvered sunshades.

Example 8. Calculate the SHGC of glazing system ID 25a if a horizontally louvered shade is added (a) on the indoor side, (b) between the glazings, and (c) on the outdoor side. The shade material has a reflectance of 0.60 and the shades are installed in the open position (0°). $\theta = 60°$ and $\Omega_V = 40°$. Also consider (d) vertical louvers located on the indoor side of the glazing with $\Omega_H = 40°$.

Solution: Use Equations (39) and (40) and values from Table 14E. From Example 6, SHGC(60°) = 0.34, and $SHGC_D = 0.36$.

(a) Indoor shade

$$IAC(60,40) = IAC_0 + (IAC_{60} - IAC_0) \times \min(1.2\Omega, 60)/60$$
$$= 0.99 + (0.87 - 0.99) \times \frac{40}{60}$$
$$= 0.91$$
$$SHGC(\theta,\Omega)_{cg,\,shaded} = IAC(60,40) \times SHGC(\theta)_{cg}$$
$$= 0.91 \times 0.34$$
$$= 0.31$$
$$SHGC_{D,\,cg,\,shaded} = IAC_D \times SHGC_{D,\,cg}$$
$$= 0.93 \times 0.36$$
$$= 0.33$$

(b) Louvers between glazings

$$IAC(60,40) = IAC_0 + (IAC_{60} - IAC_0) \times \min(1.2\Omega, 60)/60$$
$$= 0.97 + (0.68 - 0.97) \times \frac{40}{60}$$
$$= 0.78$$
$$SHGC(\theta,\Omega)_{cg,\,shaded} = IAC(60,40) \times SHGC(\theta)_{cg}$$
$$= 0.78 \times 0.34$$
$$= 0.27$$
$$SHGC_{D,\,cg,\,shaded} = IAC_D \times SHGC_{D,\,cg}$$
$$= 0.82 \times 0.36$$
$$= 0.30$$

(c) Outdoor louvers

$$IAC(60,40) = IAC_0 + (IAC_{60} - IAC_0) \times \min(1.2\Omega, 60)/60$$
$$= 0.94 + (0.15 - 0.94) \times \frac{40}{60}$$
$$= 0.41$$
$$SHGC(\theta,\Omega)_{cg,shaded} = IAC(60,40) \times SHGC(\theta)_{cg}$$
$$= 0.41 \times 0.34$$
$$= 0.14$$
$$SHGC_{D,\,cg,\,shaded} = IAC_D \times SHGC_{D,\,cg}$$
$$= 0.51 \times 0.36$$
$$= 0.18$$

(d) Vertical louvers

For the given conditions, results are the same as for part (a).

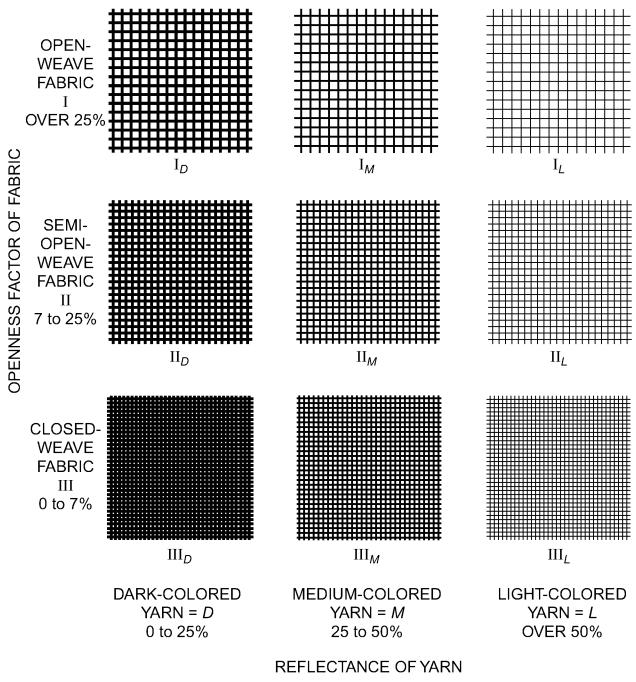
Drapery

Drapery fabrics can be classified in terms of their solar-optical properties as having specific values of fabric transmittance and reflectance. Fabric reflectance is the major factor in determining the ability of a fabric to reduce solar heat gain. Based on their appearance, draperies can also be classified by yarn color as dark, medium, and light and by weave as closed, semiopen, and open. The apparent color of a fabric is determined by the reflectance of the yarn itself. Drapery fabrics are classified into nine types, rated by openness and yarn reflectances (Figures 23 and 24).

The solar-optical properties of drapery fabrics can be determined accurately by laboratory tests (Collins et al. 2011; Kotey et al. 2009b; Yellott 1963), and manufacturers can usually supply solar transmittance and reflectance values for their products. In addition to these properties, the openness factor (ratio of the open area between the fibers to the total area of the fabric) is a useful property that can be measured exactly (Keyes 1967; Pennington and Moore 1967). Visual estimations of openness and yarn reflectance, interpreted through Figures 23 and 24, are valuable in judging the effectiveness of drapes for (1) protection from excessive radiant energy from either sunlight or sun-heated glazing, (2) brightness control, (3) providing either outward view or privacy, and (4) sound control.

To understand drapery layer solar-optical properties, the **fullness** of the drapery is needed. As simplified in Figure 25, the pleating of the drape is assumed to be square, with pleat depth w and width s. For 100% fullness, the width of fabric used is twice the width of the fenestration. If the drapery is hung flat, like a fenestration product shade, the fullness is 0%.

Table 14G presents IAC and radiant heat transfer fraction F_R values for typical glazing and shade combinations. For these types of shades, the IAC value is not strongly influenced by the incident angle of irradiation; therefore, a constant value of IAC can be used.



Kotey et al. (2009b, 2009c, 2011) and Wright et al. (2009a) contain more comprehensive discussions of models used to determine IACs of draperies.

Example 9. Calculate the SHGC of glazing system ID 25a if a drapery is added on the indoor side**.** The fabric has an openness factor of 0.05 and a yarn reflectance of 0.60, and the drapery has 100% fullness.

Solution: In Figure 24, these lines intersect in the area of designator III_L. Fabric is closed and light in color, with probable fabric reflectance of 0.52 and fabric transmittance of 0.30.

From Table 14G, both IAC and $IAC_D = 0.68$.

$$SHGC(\theta,\Omega)_{cg,\ shaded} = IAC \times SHGC(\theta)_{cg}$$

NOTE: Classes may be approximated by eye. With closed fabrics, no objects are visible through the material, but large light or dark areas may show. Semiopen fabrics do not allow details to be seen, and large objects are clearly defined. Open fabrics allow details to be seen, and the general view is relatively clear with no confusion of vision. The yarn color or shade of light or dark may be observed to determine whether the fabric is light, medium, or dark.

$$= 0.68 \times 0.34$$
$$= 0.23$$
$$SHGC_{D,\,cg,\,shaded} = IAC_D \times SHGC_{D,\,cg}$$
$$= 0.68 \times 0.36$$
$$= 0.25$$

Roller Shades and Insect Screens

In general, both roller shades and insect screens are equivalent to drapery of 0% fullness. Appropriately, much of the methodology applied to drapery fabrics applies for these devices as well.

Table 14G presents IAC for typical glazing and shade combinations. For these types of shades, the IAC value is not strongly influenced by the incident angle of irradiation; therefore, a constant value of IAC can be used.

For a more comprehensive discussion of models used to determine IACs, see Kotey et al. (2008, 2009d) for roller shades and Kotey et al. (2009e) for insect screens.

Example 10. Calculate the SHGC of glazing system ID 25a if a roller shade is added on the indoor side. The shade has an openness factor of 0.0 and a yarn reflectance of 0.65.

Solution: From Table 14G, both IAC and $IAC_D = 0.60$.

$$SHGC(\theta,\Omega)_{cg,\,shaded} = IAC(60,40) \times SHGC(\theta)_{cg}$$
$$= 0.60 \times 0.34$$
$$= 0.20$$
$$SHGC_{D,\,cg,\,shaded} = IAC_D \times SHGC_{D,\,cg}$$
$$= 0.60 \times 0.36$$
$$= 0.22$$

6. VISUAL AND THERMAL CONTROLS

The ideal fenestration system allows optimum lighting, heating, ventilation, and visibility; minimizes moisture and sound transfer between the outdoors and the indoors; and produces a satisfactory physiological and psychological environment. The controls of an optimum system react to varying climatological and occupant demands. Fixed controls may have operation or cost advantages, or both, but do not react to physical and psychological variations. Variable controls are, therefore, more effective in energy conservation and environmental satisfaction.

Operational Effectiveness of Shading Devices

Shading devices vary in their operational effectiveness. Some devices, such as overhangs, light shelves, and tinted glazings, do not require operation, have long life expectancies, and do not degrade significantly over their effective life. Other types of shading devices, especially operable indoor shades, may have reduced effectiveness because of less than optimal operation and degradation of effectiveness over time. It is important to evaluate operational effectiveness when considering the actual heat rejection potential of shading devices.

The performance of shading devices for reducing peak cooling loads and annual energy use should account for operational effectiveness or reliability in actual operation. Passive devices, such as architectural elements and glazing tinting, are considered 100% effective in operation. Glazing coatings and adherent films may degrade over time. Shade screens are removable and may be assumed to operate seasonally, but in any given population of users, some will remain in place all year long and some will not be installed or removed at optimum times. Automated shading devices controlled for optimum thermal operation are considered more effective than manual devices, but controls require ongoing maintenance, and some occupants may object to the lack of personal control with totally automated devices. Automated shading devices may also operate for nonthermal purposes such as glare and daylighting optimization, and this may reduce thermal effectiveness. Manually operated devices are subject to wide variation in use effectiveness, and this diversity in effective use should be considered when evaluating performance.

Indoor Shading Devices

Although thermal comfort of occupants may be paramount to the HVAC designer, other factors that should be considered, some of which may be more important to the user, include the following:

Radiant Energy Protection. Unshaded fenestration products become sources of radiant heat by transmitting short-wave solar radiation and by emitting long-wave radiation to dissipate some of the absorbed solar energy. In winter, glazing temperatures usually fall below room air temperature, which may produce thermal discomfort to occupants near the fenestration. In summer, individuals seated near unshaded fenestration may experience discomfort from both direct solar rays and long-wave radiation emitted by sun-heated glazing. In winter, loss of heat by radiation to cold glazing can also cause discomfort. Tightly woven, highly reflective drapes minimize such discomfort; drapes with high openness factors are less effective because they allow short- and long-wave radiation to pass more freely. Light-colored shading devices with maximum total surface usually provide the best protection because they absorb less heat and tend to lose heat readily by convection to the conditioned air.

Outward Vision. Outward vision is normally desirable in both business and living spaces. Open-weave, dark-colored fabrics of uniform pattern allow maximum outward vision, whereas uneven pattern weaves reduce the ability to see out. A semiopen weave modifies the view without completely obscuring the outdoors. Tightly woven fabrics block outward vision completely.

Privacy. Venetian blinds, either vertical or horizontal, can be adjusted and, when completely closed, afford full privacy. When draperies are closed, the degree of privacy is determined by their color and tightness of weave and the source of the principal illumination. To obscure the view so completely that not even shadows or silhouettes can be detected, fully opaque materials are used. Generally, the more brightly lit side of a partially shaded glazing is the most visible from the opposite side, making the indoors fairly private in daytime, but not at night.

Brightness Control. Visual comfort is essential in many occupied areas, and freedom from glare is an important factor in performing tasks. *Discomfort glare* is produced by uneven brightness in occupied spaces, with areas or spots that are much brighter than surrounding surfaces. Fenestrations themselves, when they look out onto bright skies or brightly reflecting surfaces, can be glare sources if care is not taken to keep surrounding brightness comparable. A maximum brightness ratio of about 3 to 1 is sometimes quoted. This ratio can be moderated by indoor furnishings and wall coverings, which on average have moderately high diffuse reflectances and access to admitted daylight. Conversely, dark indoor surfaces, and those shaded from daylight illumination, accentuate the brightness difference between the fenestration and its surroundings. Indoor surface brightness can also be elevated by ample use of indoor electric lighting, but this can have adverse consequences for the building's energy use. In general, larger fenestration apertures admit more sunlight, increasing indoor brightness without affecting the perceived brightness of the fenestration, all other factors being equal.

An important guideline is that direct sunlight must not strike the eye, and reflected sunlight from bright or shiny surfaces is equally disturbing and even disabling. A tightly woven white fabric with high solar transmittance attains such brilliance when illuminated by direct sunshine that, by contrast with its surroundings, it creates excessive glare. Off-white colors should be used so their surface brightness is not too great. Venetian blinds allow considerable light to enter by interreflection between slats. When two shading devices are used, the one on the indoors (away from the fenestration product) should be darker and more open. With this arrangement, the indoor

Notes:
[a]Louvers track so that profile angle equals negative slat angle and maximum direct beam is admitted.
[b]Louvers track to block direct beam radiation. When negative slat angles result, slat defaults to 0°.
[c]Glazing cavity width equals original cavity width plus slat width.
[d]F_R is radiant fraction; ratio of radiative heat transfer to total heat transfer, on room side of glazing system.

Notes:
[a]Louvers track so that profile angle equals negative slat angle and maximum direct beam is admitted.
[b]Louvers track to block direct beam radiation. When negative slat angles result, slat defaults to 0°.
[c]Glazing cavity width equals original cavity width plus slat width.
[d]F_R is radiant fraction; ratio of radiative heat transfer to total heat transfer, on room side of glazing system.

Notes:
[a]Louvers track so that profile angle equals negative slat angle and maximum direct beam is admitted.
[b]Louvers track to block direct beam radiation. When negative slat angles result, slat defaults to 0°.
[c]Glazing cavity width equals original cavity width plus slat width.
[d]F_R is radiant fraction; ratio of radiative heat transfer to total heat transfer, on room side of glazing system.

Notes:
[a]Louvers track so that profile angle equals negative slat angle and maximum direct beam is admitted.
[b]Louvers track to block direct beam radiation. When negative slat angles result, slat defaults to 0°.
[c]Glazing cavity width equals original cavity width plus slat width.
[d]F_R is radiant fraction; ratio of radiative heat transfer to total heat transfer, on room side of glazing system.

Notes:
[a]Louvers track so that profile angle equals negative slat angle and maximum direct beam is admitted.
[b]Louvers track to block direct beam radiation. When negative slat angles result, slat defaults to 0°.
[c]Glazing cavity width equals original cavity width plus slat width.
[d]F_R is radiant fraction; ratio of radiative heat transfer to total heat transfer, on room side of glazing system.

Notes:
[a]Louvers track so that profile angle equals negative slat angle and maximum direct beam is admitted.
[b]Louvers track to block direct beam radiation. When negative slat angles result, slat defaults to 0°.
[c] Glazing cavity width equals original cavity width plus slat width.
[d]F_R is radiant fraction; ratio of radiative heat transfer to total heat transfer, on room side of glazing system.

Notes:
[a]Louvers track so that profile angle equals negative slat angle and maximum direct beam is admitted.
[b]Louvers track to block direct beam radiation. When negative slat angles result, slat defaults to 0°.
[c]Glazing cavity width equals original cavity width plus slat width.
[d]F_R is radiant fraction; ratio of radiative heat transfer to total heat transfer, on room side of glazing system.

Table 15 Summary of Environmental Control Capabilities of Draperies

Item	Designator (Figure 23)								
	I_D	I_M	I_L	II_D	II_M	II_L	III_D	III_M	III_L
1. Protection from direct solar radiation and long-wave radiation to or from window areas	Fair	Fair	Fair	Fair	Good	Good	Fair	Good	Good
2. Effectiveness in allowing outward vision through fenestration	Good	Good	Fair	Fair	Fair	Some	None	None	None
3. Effectiveness in attaining privacy (limiting inward vision from outdoors)	None	None	Poor[a] Good[a]	Poor	Fair	Fair[a] Good[a]	Good[b]	Good[b]	Good[b]
4. Protection against excessive brightness and glare from sunshine and external objects	Mild	Mild	Mild[c] Poor[c]	Good	Good	Good[c] Poor[c]	Good	Good	Good[c] Poor[c]
5. Effectiveness in modifying unattractive or distracting view out of window	Little	Little	Some	Some	Good	Good	Blocks	Blocks	Blocks

[a]Good when bright illumination is on viewing side.
[b]To obscure view completely, material must be completely opaque.
[c]Poor rating applies to white fabric in direct sunlight. Use off-white color to avoid excessive transmitted light.

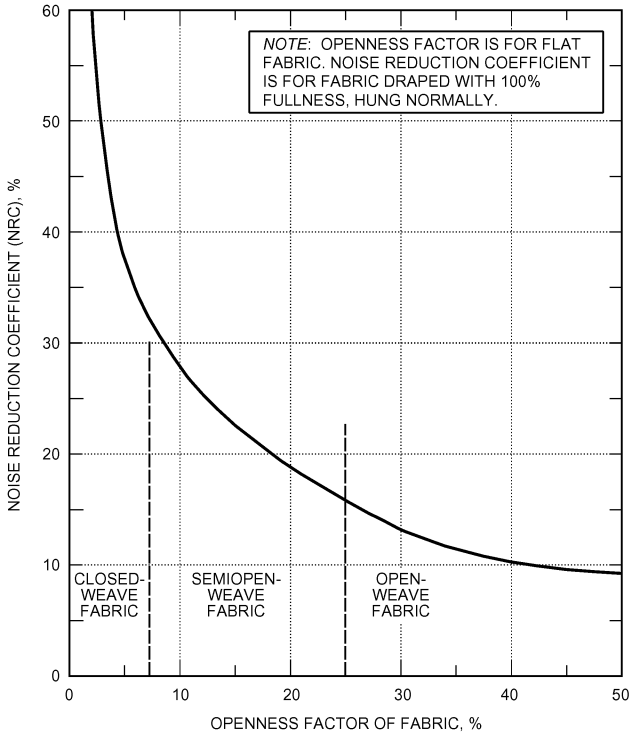

Fig. 26 Noise Reduction Coefficient Versus Openness Factor for Draperies

device can be used to control brightness for the other shading devices and, when used alone, to reduce brightness while still allowing some view of the outdoors.

View Modification. When the view is unattractive or distracting, draperies modify the view to some degree, depending on fabric weave and color (summarized in Table 15), but the fenestration product remains as an effective connection to the outdoors.

Sound Control. Indoor shading devices, particularly draperies, can absorb some sounds originating in the room but have little or no effect in preventing outdoor sounds from entering. For excessive internally generated sound, the usual remedy is to apply acoustical treatment to the ceiling and other room surfaces. Although these materials can be effective in controlling sound, they are often located on the two horizontal surfaces (ceiling and floor) and leave the opposing vertical surfaces of glazing and bare wall to reflect sound. The noise reduction coefficient (NRC = average absorptance coefficient at four frequencies) for venetian blinds is about 0.10, compared to 0.02 for glass and 0.03 for plaster. For drapery fabrics at 100% fullness, NRC ranges from 0.10 to 0.65, depending on the tightness of weave. Class III (tightly woven) fabrics have NRC values of 0.35 to 0.65. Figure 26 shows the relationship between NRC and openness factor for fabrics of normal weight.

Double Drapery

Double draperies (two sets of drapery covering the same area) have a light, open weave on the fenestration product side for outward vision and daylight when desired and a heavy, closed weave or opaque drapery on the room side to block out sunlight and provide privacy when desired. When properly selected and used, double draperies can provide a reduced U-factor and a lowered IAC. The reduced U-factor results principally from adding a semiclosed air space to the barrier.

To most effectively reduce solar heat gain, drapery exposed to sunlight should have high reflectance and low transmittance. The light, open-weave drapery should be opened when the heavy drapery is closed to prevent entry of sunlight.

Properly used double draperies give (1) extreme flexibility of vision and light intensity, (2) a lowered U-factor and IAC, and (3) improved comfort, because the room-side drapery is more nearly at room temperature. Table 14 gives characteristics of individual draperies. For large areas, the IAC should be calculated in detail to determine the cooling load.

7. AIR LEAKAGE

Infiltration Through Fenestration

Air infiltration through fenestration products affects occupant comfort and energy consumption. Infiltration is the uncontrolled inward leakage of air caused by pressure effects of wind or differences in air density, such as stack effect. Infiltration should not be confused with ventilation. Although fenestration products can be operated to intentionally provide natural ventilation and increase comfort, infiltration should be reasonably minimized to avoid unpleasant accompanying problems. If additional air is required, controlled ventilation is preferable to infiltration. Mechanical ventilation provides air in a comfortable manner and when desired. For infiltration, however, peak supply is more likely to occur as an uncomfortable draft and when least desired, such as during a storm or the coldest weather.

ASHRAE/IES *Standard* 90.1, ASHRAE's energy standard for all buildings other than low-rise residential buildings, establishes an air leakage maximum of 0.3 L/s per square metre for curtain wall and storefront fenestration and 1.0 L/s per square metre of gross fenestration product area for most other products (5.0 L/s per square metre for glazed swinging entrance doors and revolving

Licensed for single user. © 2021 ASHRAE, Inc.

doors, 2.0 L/s per square metre for nonswinging opaque doors, and 1.5 L/s per square metre for unit skylights). This air leakage is as determined in accordance with NFRC *Technical Document* 400 (NFRC 2014h) and ASTM *Standard* E283 and allows direct comparison of all fenestration products: operable and fixed, windows and doors.

Most manufactured fenestration products achieve these reasonable standards of maximum air infiltration. However, products that do not completely seal, such as jalousie windows or doors, are not likely to do so and are most appropriate for installation in unconditioned spaces.

For products achieving this infiltration standard, energy consumption caused by infiltration is likely to be significantly less than energy associated with U-factor and solar heat gain coefficient. Also, although overall air infiltration is a significant component in determining a building's heating and cooling loads, infiltration through fenestration products meeting the standard is generally likely to be a small portion of that total.

Indoor Air Movement

Because supply air grilles are frequently located directly below fenestration products, air sweeps the indoor glazing surface. Heated supply air should be directed away from the glazing to prevent large temperature differences between the center and edges of the glazing. These thermal effects must be considered, particularly when annealed glass is used and air is forced over the glass surface during the heating season. Direct flow of heated air over the glass surface can increase the heat transfer coefficient and temperature difference, causing a substantial increase in heat loss, as well as leading to thermally induced stress and risk of glass breakage.

Systems designed predominantly for cooling lower the glazing temperature and rapidly pick up the cooling load. Both tend to improve comfort conditions. However, the air-conditioned space has an increased net heat gain caused by increases in (1) solar heat gain coefficient (SHGC) caused by delivery of more of the absorbed heat to the indoor space, (2) fenestration U-factor because of the greater convection effect at the indoor surface, and (3) air-to-air temperature difference because supply air rather than room air is in contact with the indoor glazing surface. The principal increase in heat gain with clear glazing is the result of increased U-factor and air-to-air temperature difference.

8. DAYLIGHTING

8.1 DAYLIGHT PREDICTION

Daylighting is the illumination of building interiors with sunlight and sky light and is known to affect visual performance, lighting quality, health, human performance, and energy efficiency. In many European countries with predominantly cloudy skies, codes regulate minimum window size, minimum daylight factor, and window position to provide views to all occupants and to create a minimum indoor brightness level. Daylighting also provides back-up indoor illumination in the event of power outages. Daylighting may have some positive or negative health effects on the skin, eyes, hormone secretion, and mood. Its intensity, spectral content, and diurnal and temporal variation may be used to combat jet lag, sick building syndrome, and other health problems.

In terms of energy efficiency, daylighting can provide substantial whole-building energy reductions in nonresidential buildings through the use of electric lighting controls. Daylight admission can displace the need for electric lighting at the perimeter zone with vertical windows (sidelighting) and at the core zone with skylights (toplighting) and special core sunlighting systems designed to bring sunlight to core spaces and distribute it as necessary, with good lighting quality. Lighting and its associated cooling energy use constitute 30 to 40% of a nonresidential building's energy use. Energy use reductions can be achieved, perhaps less reliably, in residential buildings with manual or automated switching of electric lights on and off to match space occupancy. For internal-load-dominated buildings, daylight admission must be balanced against solar heat admission to achieve optimum energy efficiency. Because heat gains through the building envelope from solar radiation typically define peak load conditions, daylighting is also a very effective method of decreasing peak demand. Daylighting can not only decrease annual operating costs through energy efficiency, but may also reduce capital cost by mechanical system downsizing.

For daylighting designs using direct-beam sunlight entry, take care to avoid overheating and glare. Such problems can be avoided by carefully controlling or eliminating direct beam entry through orientation and shading of daylighting apertures, optical management components, and other architectural features.

For conventional sidelit nonresidential buildings, three basic relationships for daylight optimization are given as functions of (1) glazing properties and (2) fenestration area as a percent of the gross wall area:

1. Annual cooling energy use (including fan energy use) increases linearly with solar radiation admission, as indicated by the product of SHGC and WWR, but is affected (nonlinearly) by decreases in electric lighting heat gains.
2. Annual lighting energy use decreases exponentially/asymptotically with daylight admission, as indicated by the product of T_v and WWR.
3. Annual heating energy use (including fan energy use) increases linearly with decreased lighting heat gains.

Figure 27 shows the first two relationships for a prototypical nonresidential building. A similar relationship can be demonstrated with skylights. Different shading properties and control would affect electricity use differently.

The fenestration design that achieves an optimum balance between daylight admission and solar rejection can be determined by iterative calculations where the glazing area and/or glazing solar-optical properties are varied parametrically (Tzempelikos and Athienitis 2005). For each case, the following general steps should be taken for each hour over a year:

1. **Indoor Daylight Illuminance.** Determine the building characteristics, configuration, outdoor design conditions, and operating schedules as described in Chapter 18. These include building orientation, outdoor obstructions, ground reflectance, etc. Determine the depth from the window wall for each electric lighting zone. Typical sidelighting windows can effectively daylight the perimeter zone to a depth of 1.5 times the head height of the window. In private offices, one dimming zone is typically cost effective, whereas in open-plan offices, two zones are cost effective.

   Select a typical task location in each of the lighting zones. Determine indoor daylight illuminance from all window and skylight sources at these locations. Indoor illuminance may be determined using computer simulation tools or physical scale models. Comprehensive explanations of simple and computer-based tools are available (IEA 1999). The majority of these tools can model simple box geometry with noncomplex fenestration systems. Some advanced simulation tools, such as Radiance (Ward 1990) and Adeline (Erhorn and Dirksmöller 2000), can model complex geometry and fenestration systems with adequate bidirectional solar-optical data, but this capability is not routine.
2. **Lighting Energy Use.** Determine the type of lamps, ballasts, and control system to be used in the perimeter zones. Determine whether the lamp can be dimmed or switched. For example, LED and fluorescent lamps can be dimmed, but metal halides cannot be switched or dimmed. Cold, outdoor applications of some lamps may prevent switching. For electronic dimming ballasts, obtain dimming power and light output characteristics. Obtain control

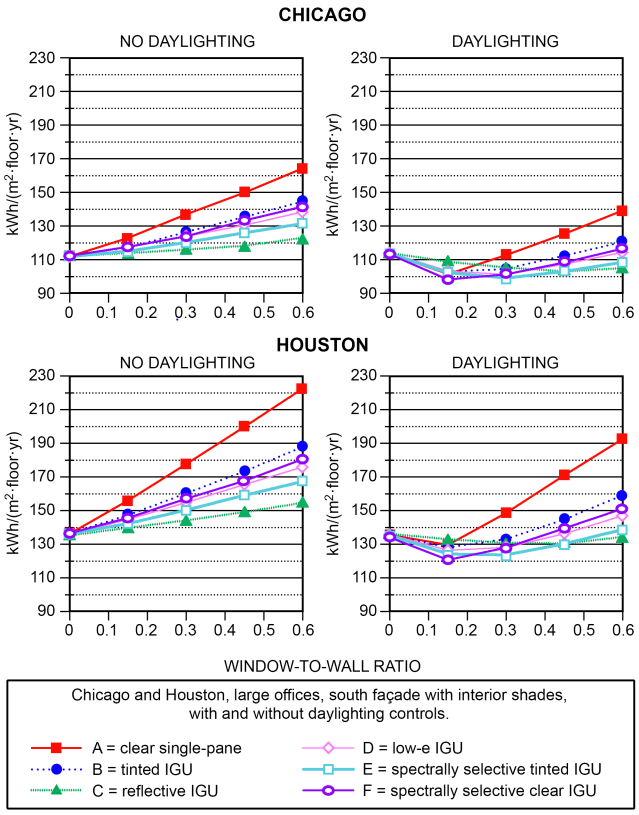

Fig. 27 Window-to-Wall Ratio Versus Annual Electricity Use in kWh/(m²·floor·year)

specifications to determine how the system will respond to available light; dead-band ranges, response times, and commissioning affect the sensitivity and accuracy of the system. The type of switching (on/off, bilevel, multilevel, and continuous dimming controls) are dictated by both the type of lamp and space use.

Determine the task illuminance design set point for each zone. Determine the percentage electric lighting power reduction $F_{daylight}$ that will result with automatic daylight controls, and apply to the installed wattage. Simplified methods for calculating lighting power reductions based on task illuminance levels are given in Robbins (1986). More sophisticated programs (Choi and Mistrick 1999) model commercially available photosensor dimming control systems (typically located in the ceiling above the work plane task) more rigorously; the spectral and bidirectional response of the photosensor to incident flux is used to determine voltage output, which is then used by the ballast controller algorithm to determine the lighting power reduction. Response delays and commissioning set points further affect this predicted output. Lights may also be switched manually, but there are very few modeling prediction tools for manual switching (Reinhart 2004). Field tests (Jennings et al. 1999) indicate that with bilevel switching, 45% of the lighting zone-hours were at less than full-power lighting, with 28% at only one-third of full lighting output levels. Manual switching occurred less in public spaces. Occupancy and other types of switching may occur as well and should be accounted for as a confounding effect with any daylighting controls.

3. **Mechanical Energy Use.** Determine mechanical energy use caused by fenestration loads and reduced electric lighting heat gains. Fenestration heat gains and losses may be computed using the section on Determining Fenestration Energy Flow. Instantaneous lighting heat gains q_{el}, described in Chapter 18, must be multiplied by the power reduction factor $F_{daylight}$.

Mechanical loads and energy use may then be determined as described in Chapter 18. Many studies have investigated the magnitude of change in heating and cooling energy use associated with reductions of lighting energy use in nonresidential buildings, as will be realized with daylighting controls. In a DOE-2.1E simulation study (Sezgen and Koomey 1998), the greatest savings were generated in hospitals, large offices, and large hotels; for every $1.00 saved through lighting energy efficiency, additional savings as a result of reduced HVAC were $0.26, $0.16, and $0.14, respectively. These results emphasize the need to include HVAC effects when assessing the effects of daylighting. Simplified design tools are available to conduct such parametric runs for preliminary analysis. Skylighting tools based on regressions using DOE-2 data or simplified DOE-2 procedures are also available [American Architectural Manufacturers Association (AAMA) 1987; Heschong et al. 1998]. More comprehensive building energy prediction tools combined with daylighting algorithms, such as DOE-2.1E (Winkelmann 1983), implement hour-by-hour calculations using existing weather data and enable evaluation of glare, visual comfort, and quality of light as well (Hitchcock et al. 2008; Lee and Selkowitz 1995; Ochoa and Capeluto 2009; Tzempelikos and Athienitis 2007).

In the United States, a general rule has been that the fenestration area should be at least 20% of the floor area. In Europe, a similar rule was based on a minimum illumination value on the normal work plane from a standard overcast sky condition. In general, it is more energy efficient to use larger fenestration areas to elevate indoor surface brightness as a glare reduction strategy than to increase indoor electric lighting levels. As fenestration area increases, indoor brightness increases while fenestration brightness remains the same. Of course, mitigating considerations include increased cost and heat transfer with larger fenestration. The latter problem can be mitigated with multiple-pane fenestration and special coatings to reduce solar gain without serious loss of light transmission, as discussed in the section on Selecting Fenestration. Orientation and shading can also be effective at mitigating glare and overheating problems.

The secondary visual benefit of fenestration is the amount and quality of light it produces in the work environment. One general rule determined the need for auxiliary electric light by assuming that daylight was adequate for a depth of two and one-half times the height of the fenestration product into the room based on a normal sill height. To prevent excessive glare, all fenestration should have sun controls. Variable and removable controls are often more effective in daylighting than fixed controls.

For more accurate evaluation of daylight distribution in a space, several prediction tools, such as the *Recommended Practice of Daylighting* (IES 1999), are available. This practice shows a simple way of calculating the daylight distribution on the work plane from windows and skylights with and without controls. Many other daylight prediction tools calculate illuminance from radiant flux transfer or ray tracing. The Illuminating Engineering Society's Daylighting Committee, Subcommittee on Daylighting Metrics, identified various instantaneous and annual measures of daylighting performance in building spaces. New techniques and improved computer tools are being developed to help calculate these measures, and various building code bodies and energy incentive programs are expected to specify daylighting performance metrics for compliance with these programs.

Any or all of the various daylight prediction tools can be used to compare the relative value of daylight distribution from alternative fenestration systems, but ultimately the designer must evaluate costs and benefits to choose between alternative designs. This may be based on energy use or, more properly, on overall costs and benefits

Licensed for single user. © 2021 ASHRAE, Inc.

to the client. Also, the risk of total loss of productivity from an electric brown-out in a space with no natural ventilation or daylight may be as important as the benefits of many energy-saving schemes.

8.2 LIGHT TRANSMITTANCE AND DAYLIGHT USE

When daylight is to be the primary lighting system, the minimum expected daylight in the building must be calculated for the building performance cycle and integrated into lighting calculations. IES (1999) gives daylight design and calculation procedures. In some glazing applications, such as artists' studios and showrooms, maximum transmittance may be required for adequate daylighting, and care is needed to maintain good color rendering when glazing tints and coatings are used. Regular clear glass, produced by float, plate, or sheet process, may be the logical choice.

When daylight is a supplementary light source, electric lighting can be designed independently of the daylight system. However, adequate switching must be included in the electric distribution to substitute available daylight for electric lighting by automatic or prescribed manual control whenever practical. Photosensitive controls automatically adjust shading devices to provide uniform illumination and reduce energy consumption. Manual control is less effective.

Buildings with large areas of glazing usually have glazing units with clear, tinted, or reflective coatings. Tinted and reflecting units reduce the brightness contrast between fenestration products and other room surfaces and provide a relatively glare-free environment for most daylight conditions.

Table 10 lists typical approximate solar energy transmittances and daylight transmittances for various glass types. Manufacturers' literature has more appropriate type-specific values.

The color of glazing chosen for a building depends largely on where and how it is used. For commercial building lobbies, showroom fenestration products, and other areas where maximum visibility from outdoors to indoors is required, regular clear glass is generally best. Clear glass with a low-e coating is also suitable for these locations, including for retail storefronts, because it only decreases light transmittance by about 10%. For other glazing areas, tinted or coated glass may best complement the indoor colors. Bronze, gray, and reflective-film glasses also give some privacy to building occupants during daylight hours. Patterned, fritted, etched, or sandblasted glass that diffuses lighting is available. In warm climates, tinted outer glazing in an insulated double-pane system can have solar heat gain rejection benefits, while providing good color-rendering illumination of the interior without apparent color.

The primary purpose of a fenestration product is not just to save energy but to provide a view of the outdoors and bring useful daylight indoors. The light-transmitting properties of fenestration systems are therefore of great importance. It is conceivable that one could design a fenestration product with excellent solar heat gain performance for hot climates (meaning a very low solar heat gain coefficient) but very poor view and daylight illumination performance. If this problem is bad enough, it can cause occupants to turn on electric lights indoors during the daytime, which adds to the electric bill and possibly causes problems of thermal discomfort as well.

The light-transmitting property of a fenestration product is called the visible **transmittance** T_v. It is similar to the solar-weighted solar transmittance, except that an additional weighting function is needed, in this case to account for the spectral response of the human eye.

In most applications, it is important to have high visible transmittance. In cooler climates, good solar heat gain is also important for offsetting wintertime heating costs. In warmer climates, low solar heat gain is good for offsetting summertime cooling costs. In the latter situation, it is difficult to have both high visible transmittance and a low solar heat gain coefficient. Figures 28 and 29 show plots of visible transmittance versus SHGC for several glazing systems covering a range of spectral selectivities (McCluney 1996). The data are for normal incidence and a single, ASTM standard solar spectral distribution.

For daylighting design, a rule of thumb is to select a glazing unit having a visible transmittance 1.5 to 2.0 times greater than its solar heat gain coefficient. For maximum light with minimum solar gain, there are fenestration products available having a visible transmittance as high as 3.0 times the SHGC. For maximizing passive solar gain (e.g., on a south orientation in a cold climate in the northern hemisphere), select a glazing unit with a low-e coating whose visible transmittance is greater than its solar heat gain coefficient.

Three different zones are delineated in Figure 29. In the **neutral zone**, it is possible to have colorless glazing systems (i.e., glazings with approximately uniform transmittance over the visible spectrum). Glazings in this zone can have some color, but this is not necessary. In the **color zone**, the only way to achieve higher visible transmittance for a given level of solar heat gain coefficient is by stripping off some of the red and blue wavelengths at the edges of

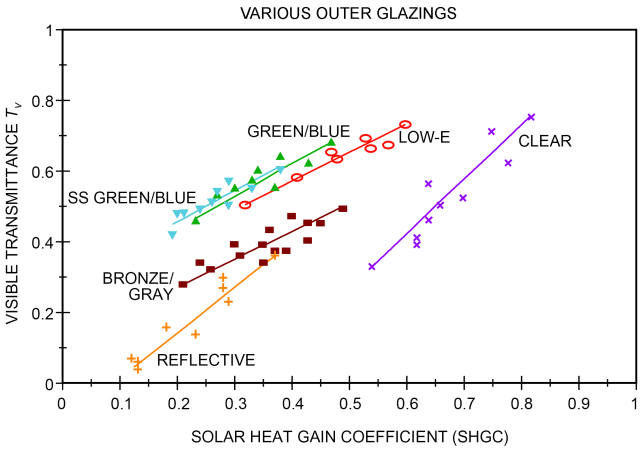

Fig. 28 Visible Transmittance Versus SHGC for Several Glazings with Different Spectral Selectivities

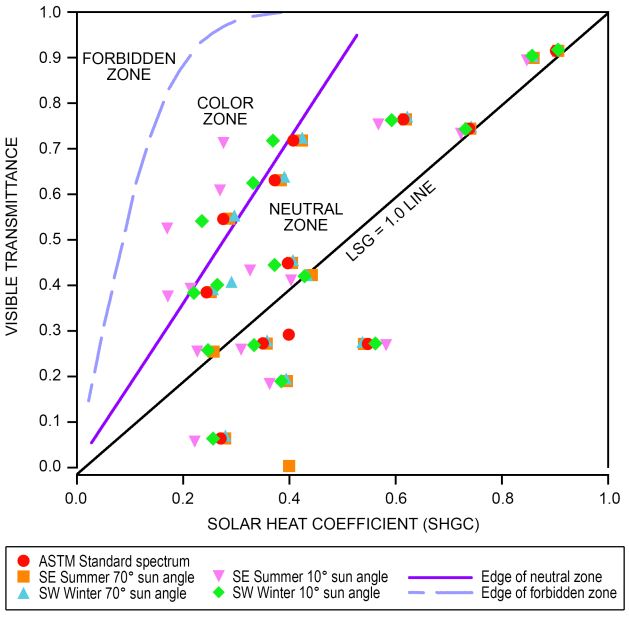

Fig. 29 Visible Transmittance Versus SHGC at Various Spectral Selectivities
(McCluney 1996)

Table 16 Spectral Selectivity of Several Glazings

Glazing	T_v	SHGC	LSG
Reflective blue-green	0.33	0.38	0.87
Film on clear glass	0.19	0.22	0.86
Green tinted, medium	0.75	0.69	1.09
Green low-e	0.71	0.49	1.45
Sun-control low-e + green	0.36	0.23	1.56
Super low-e + clear	0.71	0.40	1.77
Super low-e + green	0.60	0.30	2.00

the human spectral response function with a spectrally selective glazing transmittance, imparting color to the transmitted radiation (or by otherwise altering the spectral transmittance and hence the color over the visible portion of the spectrum). In the **forbidden zone**, no combination of visible transmittance and solar heat gain coefficient is possible for normal incidence and for the solar spectral distribution used. (Changing the solar spectral distribution used to calculate T_v and SHGC shifts the transition curves somewhat. A low solar altitude angle, direct-beam spectrum will move the curves to the left on the plot in Figure 29.) Glazings that transmit more solar radiant heat than light cluster on the lower portion of the plot.

The T_v versus SHGC chart can be a useful tool for illustrating the degree of spectral selectivity attained by a glazing system. These concepts lead to an index of spectral selectivity that can be useful. It is called the **light-to-solar-gain ratio (LSG)** (McCluney and Jindra 2001), defined as

$$\text{LSG} = \frac{T_v}{\text{SHGC}} \tag{41}$$

Some characteristic values for T_v, SHGC, and LSG are given in Table 16 for several different glazings, using the ASTM standard spectral distribution at normal incidence to calculate the values.

The LSG can be useful in spotting errors in calculating the SHGC. Values of SHGC that lie outside reasonable ranges can be spotted fairly quickly and used to identify possible problems in calculations or measurements. In general, it is very difficult and therefore unlikely to have a useful glazing system for buildings with an LSG value greater than 3.0. Values below 0.3 should be particularly suspect, because they indicate a glazing that transmits considerably more heat than light and would be unlikely candidates for general use. Generally, a high value of LSG is desired for residential buildings in hot climates, to maximize daylight admission with minimal solar heat gain. This is also true for internal-load-dominated nonresidential buildings in many climates, because solar gain rejection is often desired for such buildings, even in cool or cold climates. Provided that the fenestration product has a low-e coating, an LSG value somewhat below 1.0 is appropriate in cold climates for residential buildings and nonresidential buildings without strong internal cooling loads.

9. SELECTING FENESTRATION

Because fenestration systems provide so many functions, and because environmental conditions and user needs vary widely, it is difficult to make a completely optimal selection of a fenestration system. Considering aesthetics and cost, visual and comfort performance, annual energy costs, peak-load consequences, and acoustic characteristics, the choice is seldom optimal. The HVAC system designer, fortunately, has a more restricted range of interests, mainly dealing with the energy consequences of a particular fenestration selection. This section therefore focuses on fenestration energy performance determination.

9.1 ANNUAL ENERGY PERFORMANCE

Instantaneous energy performance indices (e.g., U-factor, solar heat gain coefficient, visible transmittance, air leakage) are typically used to compare fenestration systems under a fixed set of conditions. However, the absolute and relative effect of these indices on a building's heating and cooling load can fluctuate as environmental conditions change. Further, internal loads from electric lighting fluctuate as automatic controls dim or turn off electric lighting in response to available daylight. As a result, these indices alone are not good indicators of the annual energy performance attributable to the fenestration. Such energy performance is difficult to quantify in and of itself because of numerous dynamic responses between the fenestration system and the total environment in which it is installed. The four basic mechanisms of fenestration energy performance (thermal transfer, solar heat gains, air leakage, and daylighting) should all be taken into account but are not independent of many other parameters that influence performance. As a result, the annual energy performance of fenestration systems can be accurately determined only when many variables are considered. Building type and orientation, climate (weather, temperature, wind speed), microclimate (shading from adjacent buildings, trees, terrain), occupant usage patterns, and certain HVAC parameters can significantly affect the annual energy effects of fenestration systems.

For these reasons, the most effective means of establishing fenestration annual energy performance is through detailed, dynamic, hourly computer simulations for the specific building and climate of interest. Because instantaneous performance of fenestration often varies by differing magnitudes as climatic conditions change, the most accurate simulation results are obtained when these variances are accounted for in a building energy simulation computer program. After constructing the simulation model following the procedures defined in Chapters 17 and 18 (for residential and commercial construction, respectively), specific changes to the fenestration system can be modeled, and the annual energy performance changes attributable to fenestration can be quantified. These analytical techniques do not consider issues of performance durability for the various instantaneous indices and should only be used as an initial annual energy performance indicator (Mathis and Garries 1995).

Simplified Techniques for Rough Estimates of Fenestration Annual Energy Performance

Although dynamic hourly modeling is certainly the most accurate technique for determining fenestration annual energy performance, and software for hourly modeling now runs on most desktop and laptop computers, it is not always available to decision makers and end users of fenestration products, simply because users may not want to make the necessary inputs to run the analysis. Under these circumstances, it may be useful to assess the relative importance of, or balance the trade-off between, the known instantaneous performance indices of U-factor, SHGC, T_v, and air leakage, for any given fenestration system when considering heating, cooling, and lighting loads for many different building types and climates. Huang et al. (1999) and Mitchell et al. (1999, 2012) describe personal computer programs to run this simplified analysis for residential windows.

Broad generalizations can be made for some classifications of building types and climates. For instance, with large commercial buildings, which require substantial cooling energy use during daytime occupied hours because of high internal loads, significant thermal mass, or high orientation dependency, low SHGC is important to reduce the cooling load. Also, an evaluation of commercial fenestration annual energy use can take into account the trade-off between electric lighting and the natural daylighting benefits associated with a particular fenestration system. However, low U-factor is also important because commercial buildings have bimodal operation: they can have significant heating energy

Licensed for single user. © 2021 ASHRAE, Inc.

consumption during morning warm-up, which occurs during unoccupied predawn hours, before people arrive and lights and equipment are turned on, and before any passive solar gain. In low-rise, detached residential buildings, electric lighting loads are typically very small in comparison to the heating and cooling loads because of high envelope-dependent energy use, egress requirements, and occupant usage patterns. The slight energy benefits of daylighting may be neglected altogether when using light-emitting diode (LED) lighting, which reduces residential light loads substantially. Despite these generalizations, the problem still exists of balancing and assessing the effect of each of the remaining parameters to establish seasonal or annual energy performance for cases in which detailed computer modeling is not performed. Furthermore, in all building types, the fact that energy savings afforded by daylighting are small does not negate the desirability of well-controlled natural light: daylighting without glare or excessive contrast is an important amenity.

Developing simplified annual energy performance indices for fenestration typically involves using instantaneous fenestration performance indices to quantify building- and climate-independent scalars of annual or seasonal energy performance for rating purposes. Many of these performance indices can be relatively independent of building type, climate, distribution of products, orientation, and other items needed for hourly dynamic building energy analyses. These normalized, scalar-based approaches are also limited in accuracy for the same reasons. A further limitation of the simplified techniques is that they do not have broad applicability to varied building types (e.g., commercial versus residential buildings). The usefulness of these scalar-based approaches can be increased when limiting the comparison to a single building type. Currently, simplified techniques for characterizing fenestration annual energy performance are applicable only to fenestration systems for detached residential buildings and are not appropriate for use with multifamily residential or commercial building fenestration systems.

Where a building function requires controlling outdoor air through a door opening, evaluation of the fenestration annual energy performance involving the resulting air exchange cannot be based on instantaneous indices, but must be based on an annualized process. Evaluate an automated door product designed to limit door-opening, door-open, and door-closing times for its air exchange, air leakage, and thermal transmittance properties, and compare its performance to that of a conventionally operating automated insulated sectional door complying with U-factor and air leakage requirements. Because a door product limiting air exchange is specified in terms of the number of opening and closing cycles per day averaged over a one-year period, not only can its annual energy performance be assessed, but its heating and cooling savings can also be estimated with respect to the sectional door, assuming the same number of average cycles per day and a similar door-open time.

Simplified Residential Annual Energy Performance Ratings

Annual energy performance (AEP) ratings can provide a simple means of product comparisons for consumers. These ratings have been derived with many assumptions, usually to suit local climatic conditions.

The Canadian Standards Association (CSA *Standard* A440.2) developed a simplified energy rating applicable to residential heating in the Canadian climate, which was adopted in the 1995 *National Energy Code for Houses*. The standard also provides for specific energy ratings to compare products by orientation and climate.

In the United States, where heating and cooling are both significant, NFRC is developing a rating system that includes both effects (Arasteh et al. 2000; Crooks et al. 1995). NFRC's (2014i) *Technical Document* 901 provides guidance on how fenestration affects heating and cooling energy consumption in single-family residences.

In Australia, the Window Energy Rating Scheme (WERS; www.wers.net) publishes simplified, consumer-friendly AEP ratings for heating and cooling performance of residential windows. It displays regression-based AEP rankings as stars, on a scale of 0 to 10; one rating is for cooling performance, and another for heating. Ten stars for either heating and cooling corresponds to the "perfect" window for that purpose. As inputs, WERS uses U-factor and SHGC, determined using procedures licensed from the NFRC and the Australian Fenestration Rating Council (AFRC; www.afrc.org.au).

9.2 CONDENSATION RESISTANCE

Water vapor condenses in a film on fenestration surfaces that are at temperatures below the dew-point temperature of the indoor air. If the surface temperature is below freezing, frost forms. Sometimes, condensation occurs first, and ice from the condensed water forms when temperatures drop below freezing. Condensation frequently occurs on single glazing and on aluminum frames without a thermal break. The edge seal creates a thermal bridge at the perimeter of the glazing unit.

Circulation of fill gas caused by temperature differences in the glazing unit cavity contributes to the condensation problem at the bottom of the indoor glazing (Curcija and Goss 1994, 1995; Wright 1996b; Wright and Sullivan 1995a, 1995b). In winter, fill gas near the indoor glazing is warmed and flows up, while gas near the outdoor glazing is cooled and flows down. The descending gas becomes progressively colder until it reaches the bottom of the cavity. There, the gas turns and flows to the indoor glazing, resulting in higher heat transfer rates at the bottom. Thus, the bottom edge of the indoor glazing is cooled both by edge-seal conduction and by fill-gas convection. The combined effect of these two heat transfer mechanisms is shown in Figure 30. The surface isotherms show a wider band of cold glazing at the bottom of the window. Typical condensation patterns match these isotherms. The vertical indoor surface temperature profile also shows the effect of edge-seal conduction and that the minimum indoor surface temperature is near the bottom edge of the glazing.

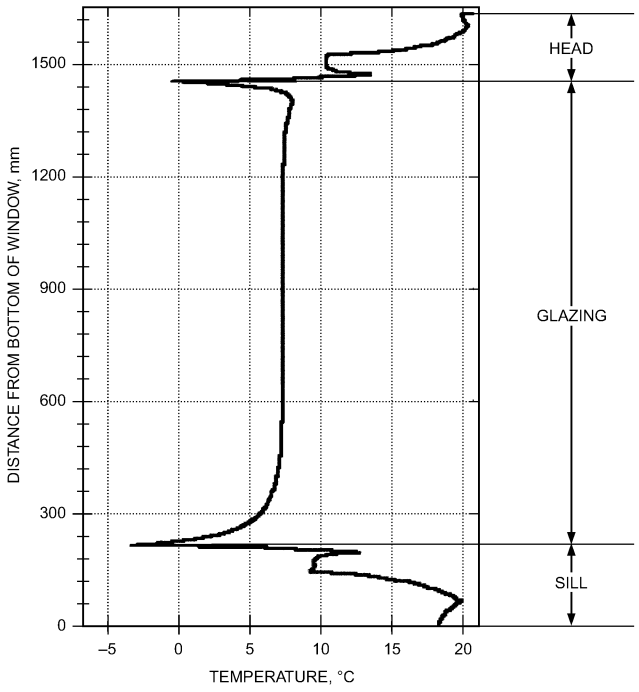

Fig. 30 Temperature Distribution on Indoor Surfaces of Glazing Unit

Licensed for single user. © 2021 ASHRAE, Inc.

Condensation on fenestration and surrounding structures can cause extensive structural, aesthetic, and health problems. Specific examples include peeling of paint, rotting of wood, saturation of insulation, and mold growth. Ice can render doors and windows inoperable and prevent egress during an emergency.

Energy-efficient housing has been accompanied by reduced ventilation. The resulting increase in indoor humidity has contributed to the condensation problem. However, the solution does not lie in the reduction of humidity levels to a minimum. Relative humidity below 20% and above 70% can increase health risks and reduce comfort. Generally, a minimum of 30% rh should be maintained, and 40% to 50% is more desirable (Sterling et al. 1985). Consequently, a better solution is to improve the fenestration product so interior surface temperatures are warmer and condensation does not occur or is minimized.

Minimum indoor surface temperatures can be quantified in a variety of ways. De Abreu et al. (1996), Elmahdy (1996), Griffith et al. (1996), Sullivan et al. (1996), and Zhao et al. (1996) demonstrated good agreement between detailed two-dimensional numerical simulation and surface temperature measurements using thermographs. Curcija et al. (1996) and Wright and Sullivan (1995c) developed simplified simulation models to predict condensation resistance. Center-glass and bottom-edge surface temperatures that can be expected for two different glazing systems exposed to a range of outdoor temperature are shown in Figure 31. Both glazing systems include insulating foam edge seals. High-performance glazing systems (e.g., low-e/argon and insulated spacers) allow significantly higher indoor humidity levels.

Current measures of condensation resistance of a fenestration system are the **condensation resistance (CR)** as defined by NFRC 500 (2014j) and its user guide (2014h), the **condensation resistance factor (CRF)** as defined by AAMA (1988), or the **temperature index (I)**, as defined in CSA *Standards* A440 and A440.1.

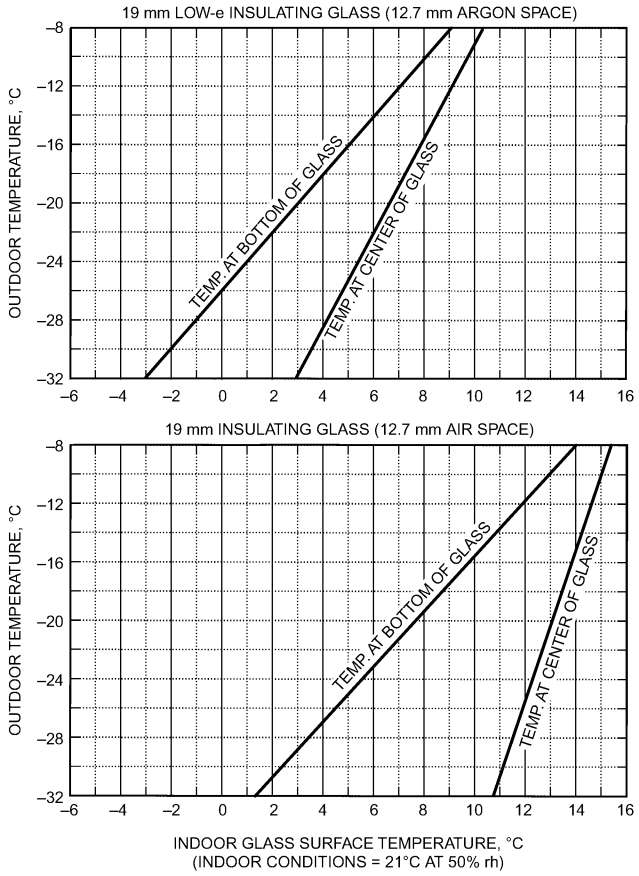

Fig. 31 Minimum Indoor Surface Temperatures Before Condensation Occurs

Note that the temperature index method in CSA *Standard* A440 stipulates that the test is performed on the fenestration with all the cracks *not* sealed. This represents a major difference between the CSA *Standard* A440 method and the AAMA and NFRC methods. There are some merits of leaving cracks unsealed during testing for condensation resistance. In particular, any inherent deficiencies in fenestration design may result in uncontrolled air leakage through the fenestration. This air leakage could not be detected or dealt with in the simulation models, and can only be seen in the results of the determined temperature index. On the other hand, there is some financial benefit to the window manufacturer in testing the fenestration for condensation resistance with cracks sealed, because one test can determine R-value and condensation resistance.

Research shows that air leakage does affect the temperature index (measure of condensation resistance as determined by CSA *Standard* A440). Elmahdy (2001, 2003) showed that sealing cracks during testing artificially improves the temperature index, compared to the results of the same window tested with cracks unsealed.

Condensation resistance is a measure of condensation potential, based on both area and temperature weighting and expressed as a minimum of center-of-glazing, edge-of-glazing, and frame CRs. The novelty of this index is that it is determined using computer simulation tools unless the overall thermal performance cannot be validated with testing. If thermal performance cannot be validated, a testing option for determining CR is used.

The other two standards define the values by a single dimensionless number as

$$\text{CRF or } I = \frac{t - t_c}{t_h - t_c} \tag{42}$$

where t_h and t_c are the warm- and cold-side temperatures, respectively. Figure 32 can be used to determine the acceptable range of CRF/I for a specific climatic zone.

The two standards differ in the methods used to determine temperature. The CSA test procedure is based on thermocouple measurements at the coldest location on the frame plus three locations on the glazing, each 10 mm above the bottom sightline. The AAMA procedure specifies two separate factors: one for the frame (CRF_F), which uses weighted frame temperature obtained from surface temperature measurements at predetermined and roving locations on the frame, and one for the glazing unit (CRF_G), which uses the average of six temperatures measured at predetermined locations near the top, middle, and bottom of the glazed area.

Indoor details can significantly alter the potential for condensation on fenestration surfaces. Items such as venetian blinds, roll blinds, insect screens, and drapes increase thermal resistance between the indoor space and fenestration and lower the temperature of the fenestration surfaces. These fenestration treatments do not prevent migration of moisture, so they can cause increased condensation. Figure 33 shows different situations that affect the potential for condensation. Note that window reveal plays an important role. If the window is placed near the outside of the wall, the increase in the outdoor film coefficient and decrease in the indoor film coefficient cause colder window surfaces. This effect is more pronounced near the corners of the recess where the indoor film coefficient is locally suppressed because air movement is restricted. Also, blinds should be placed at least 100 mm from the plane of the wall to allow some natural convection between the window and the blind.

Air leakage, especially in operable sections of fenestration, is another important cause of low surface temperature. Leakage near

Licensed for single user. © 2021 ASHRAE, Inc.

edge-of-glass sections can further increase the potential for condensation. However, the drier outdoor air decreases relative humidity near leakage sites and, in some cases, offsets the undesirable effect of lower surface temperatures. The net effect of air leakage cannot readily be determined experimentally or with simulation.

9.3 OCCUPANT COMFORT AND ACCEPTANCE

Human thermal comfort is an immediate sensation that reflects building occupants' perceived response to many physical factors. Unlike much building design that is based primarily on long-term energy and economic considerations, comfort-related design focuses on, and must take heed of, short-term responses of the body's physiology to its surroundings.

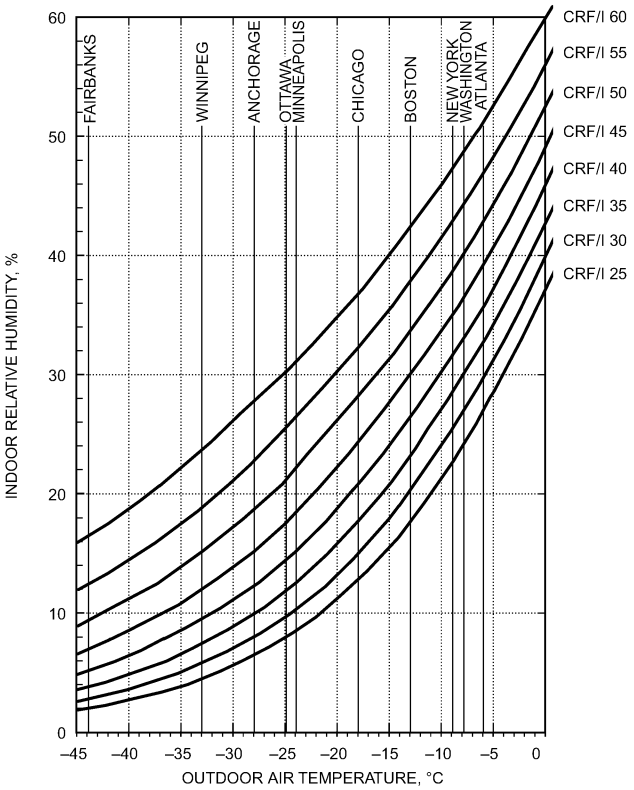

Fig. 32 Minimum Condensation Resistance Requirements (t_h = 20°C)

Fenestration influences thermal comfort through a combination of three mechanisms: long-wave radiation exchange, absorption of solar radiation, and convective draft effects (Figure 34). An understanding of these phenomena is important to help designers evaluate the benefits of improved fenestration and create comfortable buildings. Although it is well understood that high-performance fenestration can reduce building energy consumption, a better understanding of their effect on comfort might lead to further savings. For example, Hawthorne and Reilly (2000) suggest that significant energy consumption is caused by the standard practice of using perimeter duct distribution in houses to mitigate potential discomfort caused by fenestration. They found that perimeter heating is often not necessary when high-performance fenestration is installed and that heating energy savings of 10 to 15% could result from installing a simpler, less expensive duct system. Better windows can allow thermostat settings to be lowered with no loss

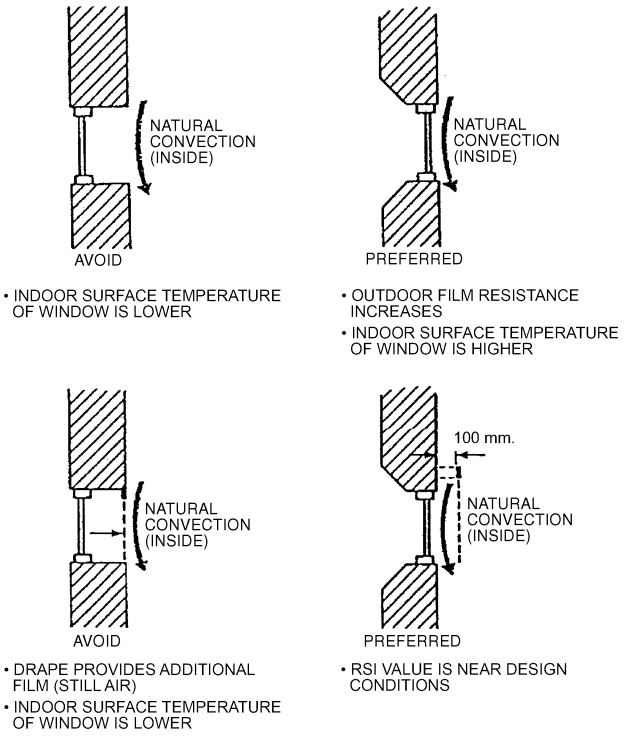

Fig. 33 Location of Fenestration Product Reveals and Blinds/ Drapes and Their Effect on Condensation Resistance

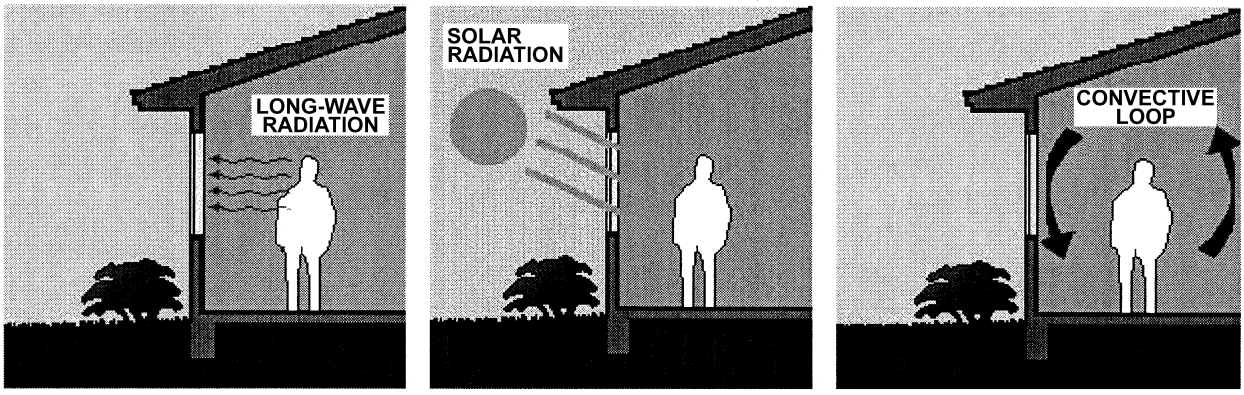

Fig. 34 Fenestration Effects on Thermal Comfort: Long-Wave Radiation, Solar Radiation, Convective Draft

Licensed for single user. © 2021 ASHRAE, Inc.

of comfort. Another simulation study (Lyons et al. 2000) examined the relative magnitudes of a residential window's physical influences under a wide variety of winter and summer climates, glazing parameters, and clothing levels. They found that

- Long-wave, thermal radiation influences of the window dominate unless direct sun strikes the occupant
- Direct solar load has a major influence on perceptions of comfort
- For most residential-size windows, draft effects are generally small

With all but highly insulating fenestration, the indoor surface temperature of the fenestration is heavily influenced by outdoor conditions, and this temperature can significantly affect radiant heat exchange between an occupant and the environment. If this heat exchange moves outside the acceptable range, discomfort results. Mean radiant temperature (MRT) is commonly used to simplify the characterization of the radiant environment. On a cold day, the indoor surface temperature can easily drop below –9°C for a clear single-pane window and below 4°C for a clear, double-pane window. If the occupant is sitting sufficiently near the window, MRT could drop to 13°C for the single-pane case and 17°C for the double-pane case. Based on ASHRAE *Standard* 55, even use of the clear double-pane window could result in discomfort. [This example assumes an outdoor air temperature of –18°C, indoor air temperature of 22°C, nonwindow surface temperatures of 22°C, occupant/window view factor of 0.3, 0.9 clo (standard winter indoor clothing), and activity level of 1 met.] In addition to the MRT effect, a cold indoor glazing surface can induce a downward draft that increases air movement, contributing to further discomfort. If direct solar radiation strikes the glazing or occupant, the situation is much more complex. Conversely, for a double-pane window with a low-e coating and a triple-pane window with two low-e coatings, the net results would be MRTs of 19°C and 21°C, respectively. Both of these would satisfy the ASHRAE *Standard* 55 criteria for comfort.

In winter, the warming effect of sunlight on skin and clothing is often welcome, depending on the compounding effect of other factors such as air temperature. Fenestration also absorbs and transmits a significant amount of solar radiation. Because of such absorption, solar-heated fenestration may improve MRT for a nearby person. The premise of passive solar design is that occupants will welcome, or at least tolerate, solar gain in exchange for savings on heating energy. However, it is desirable that the onset of discomfort be able to be predicted; otherwise, the energy-saving design may be defeated if occupants draw shades to prevent overheating.

In summer, solar-heated glazing may become uncomfortably hot and, in commercial premises, actually devalue rented space near windows. The indoor surface of body-tinted, heat-absorbing glass can routinely reach temperatures above 50°C in summer conditions, raising MRT by as much as 8 K. This can be ameliorated by adding a second glazing on the indoors. Transmitted radiation often causes discomfort if it falls directly on the occupant. A person sitting near a window in direct solar radiation can experience heat gain equivalent to a 11 K rise in MRT (Arens et al. 1986). Similarly, in residential applications, the perceived need for solar control is affected both by the contribution of window surfaces to MRT and by overheating from direct solar load.

Advances in fenestration technology, especially high-performance glazings, mean that the designer has a choice of potential glazing systems. On the basis of annual energy performance for heating, cooling, and lighting, these alternatives may give similar outcomes. However, because they represent different combinations of U-factor, SHGC, and indoor glazing surface temperature, their comfort outcomes may differ considerably. Research continues to develop tools to help designers evaluate such difficult trade-offs. In the meantime, several general rules of thumb may be followed:

- In heating-dominated climates, fenestration with the lowest U-factor tends to give the best comfort outcomes. However, there is likely to be a trade-off between the twin goals of maximizing instantaneous comfort and minimizing annual energy consumption.
- In cooling-dominated climates or for orientations where cooling loads are of concern, fenestration with the lowest rise in surface temperature for a given SHGC tends to give the best comfort outcomes.

Table 17 Sound Transmittance Loss for Various Types of Glass

Type of Glass	Sound Transmittance Loss, dB
3 mm double-strength sheet glass	24
6 mm plate or float glass	27
13 mm plate glass	32
19 mm plate glass	35
25 mm plate glass	36
6 mm laminated glass (11 mm plastic interlayer)	30
25 mm double glass	32
13 mm laminated glass (11 mm plastic interlayer)	34
Multiple-glazing unit, 150 mm air space, 6 mm plate or float glass	40

Sound Reduction

Proper acoustical treatment of outdoor walls can decrease noise levels in certain areas. The airtightness of a wall is the primary factor to consider in reducing sound transmission from outdoors. Once walls and fenestration products are tight, the choice of glazing and draperies becomes important. Draperies do not prevent sound from coming through the fenestration; they act as an absorber for sound that does penetrate. Table 17 lists average sound transmission losses for various types of glass. These averages apply for the frequency range of 125 to 4000 Hz and were determined by tests based on ASTM *Standard* E90.

Strength and Safety

In addition to its thermal, visual, and aesthetic functions, glazing for building exteriors must also perform well structurally. Wind loads are specified in most building codes, and these requirements may be adequate for many structures. However, detailed wind tunnel tests should be run for tall or unusually shaped buildings and for buildings where the surroundings create unusual wind patterns. The strength of annealed, heat-strengthened, tempered, laminated, and insulated glass is given in ASTM *Standard* E1300.

Thermal expansion and contraction can break ordinary annealed glass. This expansion and contraction can be caused by solar radiation onto partly shaded glazing, by heat traps from drop ceilings and tight-fitting drapes, or by HVAC ducts incorrectly directed toward the glazing. High-performance tinted and reflective glasses with low-e coatings are usually more vulnerable to thermal stress breakage than clear glass. Heat treating (heat strengthening or fully tempering) the glass resists thermal stress breakage. Heat-strengthened glass, although not a safety glass, is usually preferred to tempered (safety) glass because it typically has less distortion and is much less likely to have spontaneous breakage, which can occur on very rare occasions in tempered glass. Consult the glass manufacturer or fabricator for information on thermal stress performance.

Building codes may require glass in certain positions to perform with certain breakage characteristics, which can be satisfied by tempered, laminated, or wired glass. In this case, glass should meet *Code of Federal Regulations* 16CFR1201 or other appropriate breakage performance requirements.

Life-Cycle Costs

Alternative building shells should be compared to ensure satisfactory energy use and total energy budget compliance, if required. ASHRAE *Standards* 90.1 and 90.2 should be used as a starting point. A life-cycle cost model should be developed for each system

Licensed for single user. © 2021 ASHRAE, Inc.

considered. See Chapter 38 of the 2019 *ASHRAE Handbook—HVAC Applications*.

9.4 DURABILITY

Service life and long-term performance of fenestration systems depend on the durability of all the system's components. Representative samples of glazing units are usually tested (for seal durability) according to test methods to ensure the integrity of the seal. Failure of glazing units is usually indicated by loss of adhesion of sealant to the glazing; as a result, fogging occurs inside the glazing cavity.

For argon-filled units, seal failure means a loss of argon and, hence, degradation in the unit's thermal characteristics. Extensive study of the durability of glazing units filled with argon gas (Elmahdy and Yusuf 1995) indicated that, under normal conditions, argon loss by diffusion through the sealant is very small. However, when cracks or pinholes exist in the sealant, most of the argon gas escapes, which implies that stringent quality control procedures are essential for production of durable glazing units.

Degradation of organic materials and other chemical components in glazing units as a result of exposure to ultraviolet radiation is also a factor affecting durability and service life of fenestration systems. Low-e coatings on glass tend to enhance the appearance of chemical deposits on the glass surface. Also, inserting muntin bars in glazing cavities may result in excessive rates of unit failure during ultraviolet volatile (fogging) tests unless strict quality assurance processes are implemented. Current ASTM (United States) and CGSB (Canada) durability standards are being reviewed to reflect the emergence of new technologies in the fenestration industry.

A 15-year correlation study of insulating glazing units products by the Insulating Glass Manufacturers Association (IGMA) found that long-term performance and durability of glazing units correlated well with the test level to which the unit's construction had been manufactured under ASTM *Standard* E2190's specification for sealed glazing units. Units showing the highest percentage of resistance to seal failure were those tested in conformance with the ASTM *Standard* E2190 class CBA standard. Units that did not qualify to the A level showed a definite correlation to a higher percentage of failure. Field correlation studies found that units glazed in compliance with IGMA recommendations perform for longer periods than units not constructed properly, having deficiencies in the glazing system, or not meeting ASTM requirements.

Durability of fenestration systems also depends on durability of other system components, such as weatherstripping, gaskets, glazing tapes, air seals, and hardware. Wear of these elements with time and use may result in excessive air and water leakage, which affects overall performance and service life of the system. Excessive water leakage may cause damage to the fenestration product, especially the edge seal, as well as the wall section where the product is mounted. Excessive air leakage may lead to frost build-up and condensation on fenestration surfaces.

Studies conducted at the National Research Council of Canada (Elmahdy 1995) and elsewhere (Patenaude 1995) showed that, when windows are tested at high pressure and temperature differentials, they experience air leakage rates exceeding those determined at 75 Pa and zero temperature differential (conditions used in rating window air leakage in U.S. and Canadian standards). In other studies (CANMET 1991, 1993), pressure and motion cycling on windows resulted in excessive degradation in almost all performance factors, particularly condensation resistance, ease of operation, and air and water leakage.

To predict long-term performance, unit construction for glazing units should be tested and certified in accordance with ASTM *Standard* E2190 class CBA level and the requirements of IGMA or equivalent.

Durability may also affect long-term energy performance. Consequently, NFRC now requires third-party certification for sealed-glass units.

9.5 SUPPLY AND EXHAUST AIRFLOW WINDOWS

Airflow windows allow air to flow between glass panes of multilayered glazing units, to improve the window assembly's thermal performance.

Exhaust air windows allow indoor air to flow between the inner two panes of a triple-glazed window. In the cooling season, this airflow helps reduce the cooling load by transferring heat to the flowing air and discharging it to the outdoors. During the heating season, heat loss through the outer pane of the window comes mostly from exhaust airflow, which helps reduce thermal transmission loss through the window. In addition, exhaust airflow helps maintain the inner pane surface temperature close to the indoor air temperature, thus improving the thermal comfort of occupants (Haddad and Elmahdy 1998, 1999).

The **supply air window** allows outdoor air to flow between the outer two panes of a triple-glazed window and into the building. The airflow helps reduce the heating load when heat picked up by the flowing air finds its way back into the indoor space. In the cooling season, the supply air window may increase the cooling load when heat is picked up from the outer glass pane and delivered into the indoor space.

Haddad and Elmahdy (1998, 1999) provide results of computer models comparing thermal performance of supply and exhaust airflow windows with conventional windows in various locations in North America.

9.6 CODES AND STANDARDS

National Fenestration Rating Council (NFRC)

The National Fenestration Rating Council (NFRC) was formed in 1989 to respond to a need for fair, accurate, and credible ratings for fenestration products. NFRC has developed rating procedures for U-factor [NFRC (2014a) *Technical Document* 100], solar heat gain coefficient and visible transmittance [NFRC (2014d) *Technical Document* 200], optical properties [NFRC (2014c) *Technical Document* 300], air leakage [NFRC (2014f) *Technical Document* 400], and condensation resistance [NFRC (2014j) *Technical Document* 500]. To provide certified ratings, manufacturers follow the requirements in the NFRC Product Certification Program (PCP), which involves working with laboratories accredited to the NFRC Laboratory Accreditation Program (LAP), and independent certification and inspection agencies accredited through the NFRC Certification Agency Program (CAP).

NFRC (2014a) *Technical Document* 100 was the first NFRC rating procedure approved and thus the first NFRC procedure adopted into energy codes in the United States. It requires using a combination of state-of-the-art computer simulations and improved thermal testing to determine U-factors for the whole product. The next step is product certification. NFRC has a series of checks and balances to ensure that the rating system is accurately and uniformly used. Products and their ratings are authorized for certification by an NFRC-licensed independent certification and inspection agency (IA). Finally, two labels are required: the temporary label, which contains the product ratings, and a permanent label, which allows tracking back to the IA and information in the NFRC *Product Directory*. In addition to informing the buyer, the temporary label provides the building inspector with information necessary to verify energy code compliance. The permanent label provides access to energy rating information for a future owner, property manager, building inspector, lending agency, or building energy rating organization.

Licensed for single user. © 2021 ASHRAE, Inc.

This process has noteworthy features that make it superior to previous fenestration energy rating systems and correct past problems:

- The procedures provide a means for manufacturers to take credit for all the nuances and refinement in their product design and a common basis for others to compare product claims.
- Involvement of independent laboratories and the IA provides architects, engineers, designers, contractors, consumers, building officials, and utility representatives with greater confidence that the information is unbiased.
- Requiring simulation and testing provides an automatic check on accuracy. This also remedies a shortcoming of previous energy code requirements that relied on testing alone, which allowed manufacturers to perform several tests and then use the best one for code purposes.
- The certification process indicates that the manufacturer is consistently producing the product that was rated. This corrects a past concern that manufacturers were able to make an exceptionally high-quality sample and obtain a good rating in a test but not consistently produce that product.
- A readily visible temporary label can be used by the building inspector to quickly verify compliance with the energy code.
- A permanent label enables future access to energy rating information.

Although the NFRC program is similar for other fenestration characteristics, there are differences worth noting. Solar heat gain coefficient and visible transmittance ratings [NFRC (2014d) *Technical Document* 200], referenced in several codes, and condensation resistance ratings [NFRC (2014j) *Technical Document* 500] are based on simulation alone. Optical properties [NFRC (2014c) *Technical Document* 300] and emissivity [NFRC (2014g) *Technical Document* 301] are based on measurements by the manufacturer, with independent verification. Air leakage ratings [NFRC (2014h) *Technical Document* 400] are based on testing alone. For site-assembled fenestration products (e.g., curtain walls, window walls), an NFRC label certificate fulfills the labeling requirements and serves the certification purpose. A separate NFRC label certificate is required for each "individual product" in a particular project.

United States Energy Policy Act (EPAct)

In the United States, the 1992 Energy Policy Act (EPAct) required the development of national fenestration energy rating systems and specified NFRC as the preferred developer. (The U.S. Department of Energy was to establish procedures if NFRC did not.) Although this recognition provided an impetus for NFRC to develop the desired procedures and programs, the EPAct sections on energy codes have been a key factor in their implementation.

EPAct set baselines for state energy codes. The ICC 2015 *International Energy Conservation Code® (IECC®)* and ASHRAE/IES *Standard* 90.1-2016, Energy Standard for Buildings Except Low-Rise Residential Buildings, are the current successors to the versions cited in the 1992 legislation. The majority of states have adopted the predecessors to the 2015 *IECC* (including the 2012, 2009, 2006, 2003, 2000, and 1998 *IECC* and the CABO 1995 *Model Energy Code*) and to ASHRAE/IES *Standard* 90.1-2016 (i.e., ASHRAE/IES *Standard* 90.1-2013/2010/2007/2004/2001/1999/1989) into their codes either directly or by reference when adopting a building code published by one of the three national code organizations in the United States. The ICC 2015 *International Building Code* (the U.S. model building code jointly developed by ICBO, BOCA, and SBCCI) references the 2015 *IECC*.

ICC's 2015 *International Energy Conservation Code*

The ICC's 2015 *IECC* references NFRC (2014a) *Technical Document* 100 for U-factor (as did the 2012, 2009, 2006, 2003, 2000, and 1998 *IECC* and the 1995 *Model Energy Code*) and NFRC (2014d) *Technical Document* 200 for solar heat gain coefficient (SHGC) (as did the 2012, 2009, 2006, 2003, 2000, and 1998 *IECC*). Sections C303.1.1 and R303.1.3, which cover all occupancies, require U-factors and SHGCs and visible transmittances (T_vs) of fenestration products (windows, doors, and skylights) to be determined in accordance with NFRC *Technical Documents* 100 and 200 by an accredited independent laboratory, and labeled and certified by the manufacturer. The language does not specify NFRC accreditation; however, it requires both the use of the NFRC rating procedure by an independent entity, and labeling and certification. Sections C402.4.3 and R402.4.3 cite NFRC (2014h) *Technical Document* 400, and others for air leakage testing.

ASHRAE/IES *Standard* 90.1-2016

In 1999, ASHRAE and IES published a comprehensive update to *Standard* 90.1-1989 that included fenestration rating, labeling, and certification criteria in Sections 5.2.2 and 5.2.3. U-factors were to be determined in accordance with NFRC (2014a) *Technical Document* 100, solar heat gain coefficient and visible transmittance in accordance with NFRC (2014d) *Technical Document* 200, and air leakage in accordance with NFRC (2014h) *Technical Document* 400.

In 2001, ASHRAE and IES made nominal modifications to *Standard* 90.1. The most significant changes for the 2004 version were in the lighting section, with fenestration rating, labeling, and certification criteria found in Sections 5.8.2.

The 2007 revision included substantial increases in stringency for the building envelope, including both opaque assemblies and fenestration. The NFRC references remained unchanged.

The 2010 update had limited changes to the fenestration U-factor and SHGC criteria, but called for reduced air leakage. The standard began to address fenestration orientation and daylighting: in the northern hemisphere, vertical fenestration must have more area on the south side than on either the east or west side. Spaces with tall ceilings and under a roof must have a minimum skylight area for daylighting purposes. Exceptions are provided to the SHGC requirements for dynamic glazing.

The 2013 version made significant changes to fenestration U-factor and SHGC criteria. The standard expanded the consideration of daylighting by establishing criteria for a minimum VT/SHGC ratio where there is automatic control of lighting in daylight zones.

The 2016 update further changed the requirements for fenestration U-factors in most climate zones, and for SHGC in a few climate zones. Limited modifications were made to the fenestration orientation criteria.

For further information on U.S. energy codes, the Building Codes Assistance Project (BCAP) publishes a bimonthly summary entitled "Status of State Energy Codes," which provides information on current codes and pending legislation. For additional information, contact BCAP at www.bcap-energy.org.

ASHRAE/USGBC/IES *Standard* 189.1-2014

In 2006, ASHRAE, the U.S. Green Building Council (USGBC), and IES embarked on a project to develop a baseline standard for high-performance, green buildings that would apply to all buildings except low-rise residential buildings. Their *Standard* 189.1-2009 addresses sustainable sites, energy and water efficiency, the building's effect on the atmosphere, materials and resources, and indoor environmental quality (IEQ). The standard is not a rating system, but it is hoped that it will be integrated into future building rating systems.

Energy-efficiency goals for the first version of *Standard* 189.1 were to achieve a 30% additional energy savings beyond that in ASHRAE/IES *Standard* 90.1-2007. *Standard* 189.1 builds on *Standard* 90.1, but the prescriptive option in *Standard* 189.1 substitutes more stringent values in the tables and adds other criteria. For example, the prescriptive option requires that, in the northern hemisphere, vertical fenestration on the west, south, and east be shaded

Licensed for single user. © 2021 ASHRAE, Inc.

by a device or devices with a 0.50 projection factor (e.g., an overhang that is one-half as wide as the window is tall).

There were subsequent updates in 2011 and 2014.

ICC's 2015 *International Green Construction Code*™

The ICC's 2012 *International Green Construction Code*™ (*IgCC*™) is an overlay code to ICC's 2012 *IECC*. The fenestration criteria call for a 10% reduction in U-factor and SHGC from the 2012 *IECC*. The prescriptive option requires that, in the northern hemisphere, vertical fenestration on the west, south, and east be shaded by a device with a 0.25 projection factor (e.g., an overhang that is one-quarter as wide as the window is tall). The *IgCC* also allows ASHRAE/USGBC/IES *Standard* 189.1 as a compliance option.

After publication of the 2015 *International Green Construction Code*, ASHRAE and USGBC began investigating the possibilities for greater alignment between the *IgCC* and *Standard* 189.1.

Canadian Standards Association (CSA)

In Canada, the Canadian Standards Association (CSA) promulgates fenestration energy rating standards. CSA *Standard* A440.2 addresses most fenestration products, and CSA *Standard* A453 addresses doors. These are companion standards to NFRC (2014a) *Technical Document* 100. NFRC and CSA established a Thermal Harmonization Task Force to attempt to harmonize their fenestration energy rating standards.

Building Code of Australia/*National Construction Code*

In Australia, the Australian Building Codes Board maintains the *National Construction Code*, which includes the *Building Code of Australia* (BCA). The code is divided into separate volumes for residential and commercial construction. Sections 2 and 3 (residential) and Section J (commercial) set out various compliance paths for building envelope performance. Section J of the *National Construction Code* covers energy efficiency provisions for nonresidential building stock in Australia. To demonstrate compliance with Section J2 of the *National Construction Code*, the U-factor and SHGC of fenestration systems are to be rated in accordance to with Australian Fenestration Rating Council (AFRC; www.afrc.org.au), which adopts the same technical procedures as NFRC. Users should note that the energy provisions for fenestration systems are based on an energy-flow approach and do not have an upper limit for fenestration area as a percentage of gross wall area.

Complex Glazings and Window Coverings

In North America, the European Union, and Australia, fenestration rating programs are being extended to include shading devices and other nonspecular, "complex" glazing layers. These rating schemes rely on expanded capabilities of existing modeling software and measurements of basic material properties, supported by a set of industry-consensus assumptions about fitting details. However, such calculations can also be performed in "expert" mode to serve the needs of building energy modelers who require exact, rather than generalized, details.

9.7 SYMBOLS

a = absorptance in a layer, considered as an isolated layer
A = total projected area of a fenestration product; apparent solar constant
$\mathcal{A}$ = absorptance in a layer or a collection of layers (system or subsystem)
e = hemispherical emissivity
E_d = diffuse sky irradiance
E_D = direct irradiance
E_{DN} = direct normal irradiance
E_r = diffuse ground reflected irradiance
E_t = total irradiance
F_R = radiant fraction
h = surface heat transfer coefficient
k = thermal conductivity
L = glass thickness
n = refractive index
P_H = horizontal projection depth
P_V = vertical projection depth
q = instantaneous energy flux
Q = instantaneous energy flow
R = reflectance of a layer or collection of layers (system or subsystem)
R_H = height of opaque surface between fenestration product and horizontal projection
R_W = width of opaque surface between fenestration product and vertical projection
S_H = shadow height
S_W = shadow width
SHGC = solar heat gain coefficient
t = relative temperature
T = absolute temperature; transmittance of layer or collection of layers (system or subsystem)
U = overall coefficient of heat transfer
W = fenestration product width

Greek

α = material absorptivity
β = solar altitude angle
γ = surface solar azimuth
Δ = vertical projection profile angle
δ = declination
θ = incident angle
λ = wavelength
ξ = refractive angle
ρ_g = ground reflectivity
Σ = surface tilt
τ = transmissivity
ϕ = solar azimuth
Ω = horizontal projection profile angle
ϖ = solid angle

PROVIDING a comfortable and healthy indoor environment for building occupants is the primary concern of HVAC engineers. Comfort and indoor air quality (IAQ) depend on many factors, including thermal regulation; control of internal and external sources of pollutants; supply of acceptable air; removal of unacceptable air; occupants' activities and preferences; and proper construction, operation, and maintenance of building systems. Proper ventilation and infiltration are only part of achieving acceptable indoor air quality and thermal comfort. HVAC designers, occupants, and building owners must be aware of and address other factors as well. Further information on indoor environmental health may be found in Chapter 10. Changing ventilation and infiltration rates to solve thermal comfort problems and reduce energy consumption can affect indoor air quality and may be against building code or other regulations, so any changes should be approached with care and be under the direction of a registered professional engineer with expertise in HVAC analysis and design.

HVAC design engineers and others concerned with building ventilation and indoor air quality should obtain a copy of ASHRAE *Standard* 62.1 or 62.2, or those for specific applications (e.g., *Standard* 170 for health care), whichever is most relevant to the project. These standards are reviewed regularly and contain ventilation design and evaluation requirements for commercial and institutional (*Standard* 62.1) and residential (*Standard* 62.2) buildings, respectively. When designing a new building or analyzing an existing building, check which version of *Standard* 62 has been adopted by the local code authority. An existing building may be required to meet the current version of the standard, or allowed to comply with an older version. The last chapter of each year's *ASHRAE Handbook* (Chapter 39 of this volume) has a list of current standards.

This chapter addresses commercial and institutional buildings, where ventilation concerns usually dominate (though infiltration should not be ignored), and single- and multifamily residences, where infiltration has traditionally been considered most important but ventilation issues have received increased attention in recent years. Basic concepts and terminology for both are presented before more advanced analytical and design techniques are given. Ventilation of industrial buildings is covered in Chapter 31 of the 2015 *ASHRAE Handbook—HVAC Applications*. However, many of the fundamental ideas and terminology presented in this chapter can also be applied to industrial buildings.

Sustainable Building Standards and Rating Systems

Good indoor air quality is necessary for maintaining health and high productivity. Consequently, sustainable building standards such as ASHRAE *Standard* 189.1 and building rating systems, such as U.S. Green Building Council's (USGBC) Leadership in Energy and Environmental Design™ (LEED®) program, place great importance on creating and maintaining acceptable IAQ. In fact, the LEED rating system was first developed to address IAQ concerns, and roughly one-quarter of the available credit points for new commercial buildings are still IAQ related. Preparers of such rating systems, like others, have struggled with how to characterize complex ventilation and infiltration issues. These issues are addressed in detail by many portions of this chapter; separate ASHRAE design guides, manuals, books, and standards; and the references cited; these sources also provide methods to demonstrate the effectiveness of various HVAC systems and techniques in providing good IAQ in residential, commercial, and other buildings. In all designs, care is needed to eliminate excessive ventilation (e.g., beyond that needed for IAQ or by an air-side economizer) to avoid inappropriately increasing energy use. Increasing the ventilation rate above that required by *Standard* 62.1, for example, does not necessarily increase the acceptability of the indoor air quality.

The preparation of this chapter is assigned to TC 4.3, Ventilation Requirements and Infiltration.

1. BASIC CONCEPTS AND TERMINOLOGY

Outdoor air that flows through a building is often used to dilute and remove indoor air contaminants. However, the energy required to condition this outdoor air can be a significant portion of the total space-conditioning load. The magnitude of outdoor airflow into the building must be determined to size the HVAC equipment properly, and to evaluate energy consumption (if required). For buildings without mechanical cooling and dehumidification, proper ventilation and infiltration airflows are important for providing acceptable IAQ and better thermal comfort for occupants. ASHRAE *Standard* 55 specifies conditions under which 80% or more of the occupants in a space will find it thermally acceptable. Chapter 9 of this volume also addresses thermal comfort.

Airflow into buildings and between zones also affects fires, smoke movement, and safe occupant egress. Smoke management is addressed in Chapter 54 of the 2019 *ASHRAE Handbook—HVAC Applications*.

Ventilation and Infiltration

Air exchange of outdoor air with air already in a building can be divided into two broad classifications: ventilation and infiltration.

Ventilation is intentional introduction of air from the outdoors into a building; it is further subdivided into natural and mechanical ventilation. **Natural ventilation** is the flow of air through open windows, doors, grilles, and other planned building envelope penetrations. **Mechanical** (or **forced**) ventilation, shown in Figure 1, is the intentional movement of air into and out of a building using fans, ductwork, intake louvers, and exhaust grilles, for example.

Infiltration is the flow of outdoor air into a building through cracks and other unintentional openings and through the normal use

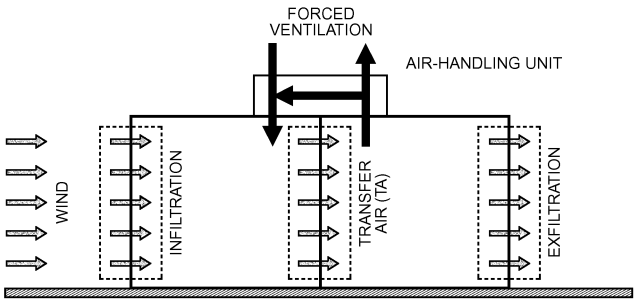

Fig. 1 Two-Space Building with Mechanical Ventilation, Infiltration, and Exfiltration

of exterior doors for entrance and egress. Infiltration is also known as **air leakage** into a building. **Exfiltration**, depicted in Figure 1, is leakage of indoor air out of a building through similar types of openings. Like natural ventilation, infiltration and exfiltration are driven by natural and/or artificial pressure differences. These forces are discussed in detail in the section on Driving Mechanisms for Ventilation and Infiltration. **Transfer air** is air that moves from one interior space to another, either intentionally or not.

Ventilation and infiltration differ significantly in how they affect energy consumption, air quality, and thermal comfort, and can each vary with weather conditions, HVAC system operation, and building use. Although one mode may be expected to dominate in a particular building, both must be considered in the proper design and operation of an HVAC system. Seasonal weather and other transient factors must be considered, as well.

Ventilation Air

Ventilation air is air used to provide acceptable indoor air quality. It may be composed of mechanical or natural ventilation, infiltration, suitably treated recirculated air, transfer air, or an appropriate combination, although the allowable means of providing ventilation air varies in standards and guidelines.

Modern commercial and institutional buildings normally have mechanical ventilation and are usually intended to be pressurized somewhat to reduce or eliminate infiltration. Mechanical ventilation has the greatest potential for control of air exchange when the system is properly designed, installed, and operated; it should provide acceptable indoor air quality and thermal comfort when ASHRAE *Standards* 55 and 62.1's requirements are followed, although issues (e.g., unusually strong pollutant sources) can still result in unacceptable indoor environment conditions. Mechanical ventilation equipment and systems are described in Chapters 1, 4, and 10 of the 2020 *ASHRAE Handbook—HVAC Systems and Equipment*.

In commercial and institutional buildings, natural ventilation (e.g., through uncontrolled use of manually operated windows) may not be desirable from the points of view of energy conservation, comfort, security, or control of airborne pollen or other pollutants in some climates and locations. In commercial and institutional buildings with mechanical cooling and ventilation, an automatically controlled air- or water-side economizer may be preferable to operable windows for taking advantage of cool outdoor conditions when interior cooling is required. When moderate outdoor temperatures occur, an air-side economizer control scheme may not only increase the rate of ventilation but also operate the cooling equipment to optimize energy use (**hybrid** or **mixed mode**).

Infiltration may be significant in commercial and institutional buildings too, especially in tall, leaky, or partially pressurized buildings and in lobby and loading dock areas. The joint between roof decking and outer walls is often particularly leaky in commercial and other large buildings, and should be properly detailed, constructed, and inspected.

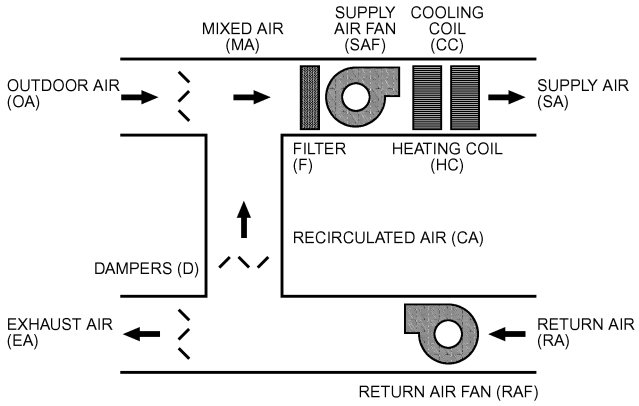

Fig. 2 Simple All-Air Air-Handling Unit with Associated Airflows

In most of the United States, residential buildings have historically relied on infiltration and natural ventilation to meet their ventilation air needs. Neither is reliable for ventilation air purposes because they depend on weather conditions, building construction, occupants, and maintenance. Natural ventilation, usually through operable windows and screened doors, is more likely to allow occupants to control indoor airborne contaminants and interior air temperature, but it can have a substantial energy cost if used while the residence's heating or cooling equipment is operating. Opened windows and doors also may lead to security, noise, or other concerns.

In place of or in addition to operable windows, small exhaust fans should be provided for localized venting of residential spaces with high pollutant levels or moisture (e.g., kitchens, bathrooms). Not all local building codes require that such exhaust be vented to the outdoors, but it is required by ASHRAE *Standard* 62.2. Instead, a local code may allow the air to be treated and returned to the space or to be discharged to an attic space. Poor maintenance of these recirculating treatment devices can make nonducted vents ineffective for ventilation purposes. Warm exhaust air can hold much moisture, so condensation in attics should be avoided. If not already required by code, consider venting attached garages and other storage spaces to the outdoors, as well.

Increasingly, building codes require general mechanical ventilation in residences. Heat recovery heat exchangers are popular for reducing energy consumption, especially in cold climates. Residential buildings with low rates of infiltration and natural ventilation, including most new buildings, require mechanical ventilation at rates given in ASHRAE *Standard* 62.2.

Forced-Air Distribution Systems

Figure 2 shows a simple **air-handling unit (AHU)** or **air handler** that conditions air for a building. Air brought back to the air handler from the conditioned space is **return air (RA)**. The return air either is discharged to the environment **[exhaust air (EA)]** or is reused **[recirculated air (CA)]**. Air brought in intentionally from the environment is **outdoor air (OA)**. Because outdoor air may need treatment to be acceptable for use in a building, it should not be called "fresh air." Outdoor and recirculated air are combined to form **mixed air (MA)**, which is then conditioned and delivered to the spaces served as **supply air (SA)**. Any portion of the mixed air that intentionally or unintentionally circumvents conditioning is **bypass air (BA)**. Because of the wide variety of air-handling systems, the airflows shown in Figure 2 may not all be present in a particular system as defined here. Also, more complex systems may have additional airflows.

Licensed for single user. © 2021 ASHRAE, Inc.

In HVAC design, volumetric airflow rates Q are normally reported in litres per second (L/s) or cubic metres per second (m^3/s). The incorrect term "volume" should not be used to describe airflow rates.

Outdoor Air Fraction

The outdoor airflow introduced to a building or zone by an air-handling unit can also be described by the **outdoor air fraction** X_{oa}, which is the ratio of the volumetric flow rate Q of outdoor air brought in by the air handler to the total supply airflow rate:

$$X_{oa} = \frac{Q_{oa}}{Q_{sa}} = \frac{Q_{oa}}{Q_{ma}} = \frac{Q_{oa}}{Q_{oa} + Q_{ca}} \quad (1)$$

When expressed as a percentage, the outdoor air fraction is called the **percent outdoor air**. The design outdoor airflow rate Q_{oa} for a building's or zone's ventilation system is found by applying the requirements of ASHRAE *Standard* 62.1 or 62.2 to that specific building, occupancy, and HVAC system. The supply airflow rate Q_{sa} is that required to meet the thermal load. The outdoor air fraction and percent outdoor air then describe the degree of recirculation, where a low value indicates a high rate of recirculation, and a high value shows little recirculation. Conventional all-air air-handling systems for commercial and institutional buildings often have approximately 10 to 40% outdoor air.

100% outdoor air means no recirculation of return air through the air-handling system. Instead, all the supply air is treated outdoor air, also known as **makeup air (KA)**, and all return air is discharged directly to the outdoors as **relief air (LA)**, via separate or centralized exhaust fans or relief dampers and grilles. An air-handling unit that provides exclusively 100% outdoor air to offset air that is exhausted is typically called a **makeup air unit (MAU)**.

When outdoor air via mechanical ventilation is used to provide ventilation air, as is common in commercial and institutional buildings and increasingly in residences, this outdoor air is usually delivered to spaces as all or part of the supply air. With a variable-air-volume (VAV) system, the outdoor air fraction of the supply air may need to be increased when supply airflow is reduced to meet a particular thermal load. In some HVAC systems, such as a dedicated outdoor air system (DOAS), conditioned outdoor air may be delivered separately from the way the spaces' loads are handled (Mumma and Shank 2001).

Room Air Movement

Air movement within spaces affects the diffusion of ventilation air and, therefore, indoor air quality and comfort. Two distinct flow patterns are commonly used to characterize air movement in rooms: displacement flow and entrainment flow. **Displacement flow**, shown in Figure 3, is the movement of air within a space in a piston- or plug-type motion. Ideally, no mixing of the room air occurs, which is desirable for removing pollutants generated within a space. Air mixing does occur, however, to various degrees. A laminar-flow air distribution system that is intended to sweep air across a space with reduced turbulence and mixing may produce a high degree of displacement flow and thus more effective pollutant removal. The pollutants' buoyancy and occupants' thermal comfort are concerns when deciding on the intended direction of airflow.

Entrainment flow, shown in Figure 4, is also known as **conventional mixing**. Systems with ceiling-based supply air diffusers and return air grilles are common examples of air distribution systems that produce entrainment flow. Airborne pollutants are removed by dilution by the ventilation air that is delivered as all or part of the supply air. Entrainment flow with very poor mixing in the room has been called **short-circuiting flow** because much of the supply air leaves the room without mixing with room air. There is little evidence that properly designed, installed, and operated air distribution

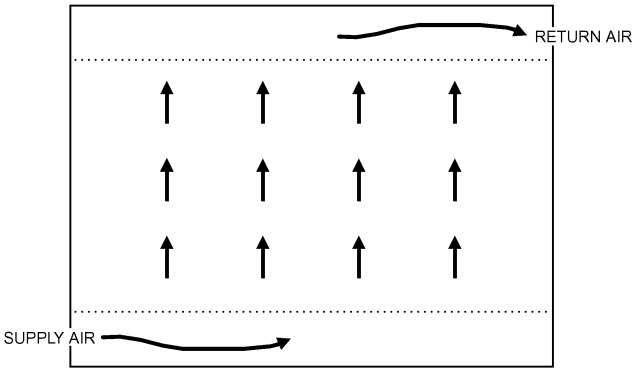

Fig. 3 Displacement Flow Within a Space

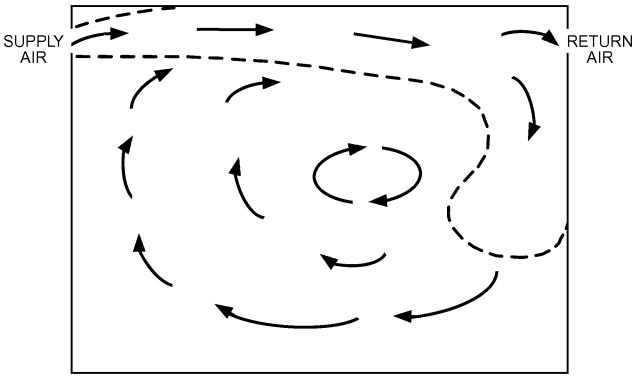

Fig. 4 Entrainment Flow Within a Space

systems exhibit substantial short circuiting, although poorly designed, installed, or operated systems may short circuit (especially ceiling-based systems in heating mode) to a higher degree (Offermann and Int-Hout 1989).

Theoretical perfect mixing occurs when supply air is instantly and evenly distributed throughout a space. Perfect mixing is also known as **complete** or **uniform mixing**; the air may be called **well stirred** or **well mixed**. This theoretical performance is approached by entrainment flow systems that have good mixing and by displacement flow systems that allow too much mixing (Rock et al. 1995). The outdoor air requirements given in the minimum ventilation rate in breathing zone table of ASHRAE *Standard* 62.1 assume delivery of ventilation air with perfect mixing within spaces. For more detailed information on space air diffusion, see Chapter 20.

Underfloor air distribution (UFAD or **UAD)**, as shown in Figure 5, is a hybrid method of conditioning and ventilating spaces (Bauman and Daly 2003). Air is introduced through a floor plenum, with or without branch ductwork or terminal units, and delivered to a space by floor-mounted diffusers. These diffusers encourage air mixing near the floor to temper the supply air for thermal comfort. The combined air then moves vertically through the space, with reduced mixing, toward returns or exhausts placed in or near the ceiling. This vertical upward movement of the air is in the same direction as the thermal and contaminant plumes created by occupants and common equipment. The ventilating performance of UFAD systems is thus often between floor-to-ceiling displacement flow and uniform mixing.

Supply air that enters a space through a diffuser, grille, or nozzle is also known as **primary air**. An air **jet** is formed as this primary air leaves the supply air outlet. **Secondary air** is the room air entrained into the jet. **Total air** is the combination of primary and

Licensed for single user. © 2021 ASHRAE, Inc.

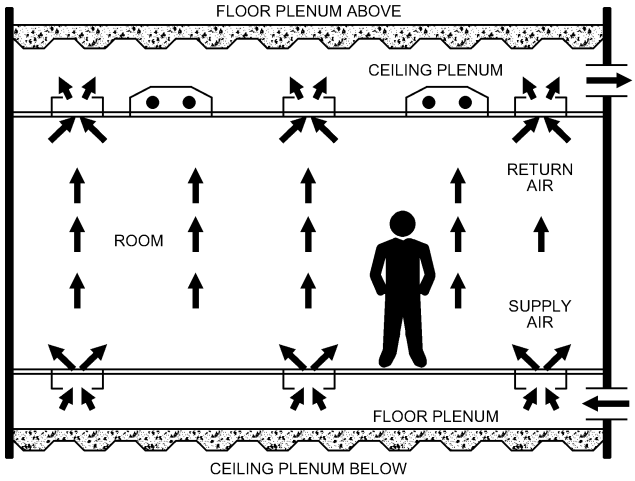

Fig. 5 Underfloor Air Distribution to Occupied Space Above
(Rock and Zhu 2002)

secondary air at a specific point in a jet and increases with distance from the outlet as is described further in Chapter 20. The term **primary air** is also used to describe supply air provided to fan-powered mixing boxes by a central air-handling unit.

For evaluation of indoor air quality and thermal comfort, rooms are often divided into two portions: the **occupied zone** and the remaining volume of the space. Often, this remaining volume is solely the space above the occupants and is referred to as the **ceiling zone**. The occupied zone is usually defined as the lowest 1.8 m of a room, although layers near the floor and walls are sometimes deducted from it; when these deductions are made, the occupied zone is sometimes renamed the **breathing zone**. Ceiling and floor plenums are not normally included in the occupied or ceiling zones. **Thermal zones** are different from these room air zones, and are defined for HVAC subsystems and their controls.

Air Change Rate

The **air change** (or **exchange**) **rate** I compares airflow to the space's volume and is

$$I = Q/V \tag{2}$$

where

Q = volumetric flow rate of air into space, m^3/s
V = interior volume of space, m^3

The air change rate has units of 1/time, usually h^{-1}. When the time unit is hours, the air change rate is also called **air changes per hour (ACH)**, with units of h^{-1}. The air change rate may be defined for several different situations. For example, the air change rate for an entire building or thermal zone served by an air-handling unit compares the amount of outdoor air brought into the building or zone to the total interior volume. This **nominal air change rate** I_N is

$$I_N = Q_{oa}/V \tag{3}$$

where Q_{oa} is the outdoor airflow rate including ventilation and infiltration. I_N describes the outdoor air ventilation rate entering a building or zone. It does not describe recirculation or the distribution of ventilation air to each space in a building or zone.

For a particular space, the **space air exchange rate** I_S compares the supply airflow rate Q_{sa} to the volume of that space:

$$I_S = Q_{sa}/V \tag{4}$$

For a particular space or zone, I_S includes recirculated as well as any outdoor air in the supply air, and is used frequently in evaluating supply air outlet performance and space air mixing.

Time Constants

Time constants τ, which have units of time (usually in hours or seconds), are also used to describe ventilation and infiltration. One time constant is the time required for one air change in a building, zone, or space if ideal displacement flow existed. It is the inverse of the air change rate:

$$\tau = 1/I = V/Q \tag{5}$$

The **nominal time constant** compares the interior volume of a building or zone to the volumetric outdoor airflow rate:

$$\tau_N = V/Q_{oa} \tag{6}$$

Like the nominal air change rate, τ_N does not describe recirculation of air in a building or zone, or characterize the distribution of the outdoor air to individual spaces in a building or zone.

The **space time constant** compares the interior volume of a particular space to the total supply airflow rate to that space. The space time constant is the inverse of the space air change rate:

$$\tau_S = V/Q_{sa} \tag{7}$$

The space time constant includes the effect of recirculated air that is part of the supply air as well as that of outdoor air introduced to the space through the supply air. If infiltration is significant in a space, then the infiltration flow rate should be included when determining both the space air change rate and the space time constant.

Averaging Time-Varying Ventilation Rates

When assessing time-varying ventilation in terms of controlling indoor air quality, the quantity of interest is often the temporal average rather than the peak. The concept of **effective ventilation** (Sherman and Wilson 1986; Yuill 1986, 1991) describes the proper ventilation rate averaging process. In this concept, the average (effective) rate is the steady-state rate that yields the same average contaminant concentration over the period of interest in the occupied space as does the actual sequence of time-varying discrete ventilation rates over the same period and in the same space. This effective rate is only equal to the simple arithmetic average rate when the discrete ventilation rates are constant over the period of interest and the contaminant concentration has reached its steady-state value. Simple arithmetic averaging of instantaneous ventilation rates or concentrations cannot generally be used to determine these averages because of the nonlinear response of indoor concentrations to ventilation rate variations.

An important constraint in the effective ventilation concept is that the contaminant source strength F must be constant over the period of interest or must be uncorrelated with the ventilation rate. These conditions are satisfied in many residential and commercial buildings because the emission rates of many contaminants that are controlled by whole-building ventilation systems vary slowly. Sherman and Wilson (1986) describe how to deal with pollutants that have stepped but otherwise constant emission rates. Pollutants such as carbon monoxide, radon, and formaldehyde, whose emission rates can be affected by ventilation, cannot be properly characterized with this concept and require more complex analyses. For constant-source-strength pollutants, the relationship between effective air change rate, effective ventilation rate, volumetric flow, source strength, average concentration, and time-averaged effective turnover time is given by

$$I_m = \frac{\overline{Q}}{V} = \frac{F}{V\overline{C}} = \frac{1}{\overline{\tau}_e} \tag{8}$$

Licensed for single user. © 2021 ASHRAE, Inc.

The time-averaged effective turnover time $\bar{\tau}_e$ in Equation (8) represents the characteristic time for the concentration in the occupied space to approach steady state over the period of interest. It can be determined from a sequence of discrete, instantaneous ventilation air change rates I_i using the following (Sherman and Wilson 1986):

$$\bar{\tau}_e = \frac{1}{N}\sum_{i=1}^{N}\tau_{e,i} \tag{9}$$

$$\text{for } I_i > 0, \tau_{e,i} = \frac{1 - \exp(-I_i \Delta t)}{I_i} + \tau_{e,i-1}\exp(-I_i \Delta t) \tag{10}$$

$$\text{for } I_i = 0, \tau_{e,i} = \Delta t + t_{e,i-1} \tag{11}$$

where

Δt = length of each discrete time period
$\bar{\tau}_e$ = time-averaged effective turnover time
$\bar{\tau}_{e,i}$ = instantaneous turnover time in period *i*
$\bar{\tau}_{e,i-1}$ = instantaneous turnover time in previous period

ASHRAE *Standard* 62.2 provides a set of factors to help calculate the annual effective air exchange rate.

Age of Air

The **age of air** θ_{age} (Sandberg 1981) is the length of time *t* that some quantity of outdoor air has been in a building, zone, or space. The "youngest" air is at the point where outdoor air enters the building by mechanical or natural ventilation, or through infiltration (Grieve 1989). The "oldest" air may be at some location in the building or in the exhaust air. When the characteristics of the air distribution system are varied, age of air is inversely correlated with quality of outdoor air delivery. Units are of time, usually in seconds or minutes, so it is not a true efficiency or effectiveness measure. The age of air concept, however, has gained wide acceptance in Europe.

The age of air can be evaluated for existing buildings using tracer gas methods. Using either the decay (step-down) or growth (step-up) tracer gas method and assuming perfect mixing, the zone average or **nominal age of air** $\theta_{age,N}$ can be determined by taking concentration measurements in the exhaust air. The **local age of air** $\theta_{age,L}$ is evaluated through tracer gas measurements at any desired point in a space, such as at a worker's desk. When time-dependent data of tracer gas concentration are available, the age of air can be calculated from

$$\theta_{age} = \int_{t=0}^{\infty} \frac{C_{in} - C}{C_{in} - C_o}\, dt \tag{12}$$

where C_{in} is the concentration of tracer gas being injected.

Because evaluation of the age of air requires integration to infinite time, an exponential tail is usually added to the known concentration data (Farrington et al. 1990).

Air Change Effectiveness

Ventilation effectiveness is a description of an air distribution system's ability to remove internally generated pollutants from a building, zone, or space. **Air change effectiveness** is a description of an air distribution system's ability to deliver ventilation air to a building, zone, or space. The HVAC design engineer usually does not have knowledge or control of actual pollutant sources within buildings, so the minimum prescribed ventilation rates of ASHRAE *Standard* 62.1 define outdoor air requirements for typical, expected building uses. For most projects, therefore, air change effectiveness is of more relevance to HVAC system design than ventilation effectiveness. Various definitions for air change effectiveness have been proposed. The specific measure that meets local code requirements must be determined, if any is needed at all.

Air change effectiveness measures ε_I are nondimensional gages of ventilation air delivery. One common definition of air change effectiveness is the ratio of a time constant to an age of air:

$$\varepsilon_I = \tau/\theta_{age} \tag{13}$$

The **nominal air change effectiveness** $\varepsilon_{I,N}$ shows the effectiveness of outdoor air delivery to the entire building, zone, or space:

$$\varepsilon_{I,N} = \tau_N/\theta_{age,N} \tag{14}$$

where the nominal time constant τ_N is usually calculated from measured airflow rates.

The **local air change effectiveness** $\varepsilon_{I,L}$ shows the effectiveness of outdoor air delivery to one specific point in a space:

$$\varepsilon_{I,L} = \tau_N/\theta_{age,L} \tag{15}$$

where τ_N is found either through airflow measurements or from tracer gas concentration data. An $\varepsilon_{I,L}$ value of 1.0 indicates that the air distribution system delivers air equivalent to that of a system with perfectly mixed air in the spaces. A value less than 1.0 shows less than perfect mixing with some degree of stagnation. A value of $\varepsilon_{I,L}$ greater than 1.0 suggests that a degree of plug or displacement flow is present at that point (Rock 1992).

An HVAC design engineer often assumes that a properly designed, installed, operated, and maintained air distribution system provides an air change effectiveness of about 1. However, the zone air distribution table of ASHRAE *Standard* 62.1 provides some estimates of effectiveness for operating in heating or cooling mode, and with various air distribution techniques. These values are then adjusted for commercial and institutional building design when the ventilation rate procedure (VRP) is used. If the IAQ procedure of *Standard* 62.1 is used, then actual pollutant sources and the air change effectiveness must be known for the successful design of HVAC systems that have fixed ventilation airflow rates.

ASHRAE *Standard* 129 describes a method for measuring air change effectiveness of mechanically vented spaces and buildings with limited air infiltration, exfiltration, and air leakage with surrounding indoor spaces.

2. TRACER GAS MEASUREMENTS

The only reliable way to determine an existing building's air change rate is to measure it. Several tracer gas measurement procedures exist (e.g., ASTM *Standard* E741 test method), all involving an inert or nonreactive gas used to label the indoor air (Charlesworth 1988; Dietz et al. 1986; Fisk et al. 1989; Fortmann et al. 1990; Harrje et al. 1981, 1990; Hunt 1980; Lagus 1989; Lagus and Persily 1985; Persily 1988; Persily and Axley 1990; Sherman 1989a, 1989b, 1990; Sherman et al. 1980). The tracer is released into the building in a specified manner, and the concentration of the tracer in the building is measured through time and related to the building's air change rate. Various tracer gases and associated concentration detection devices have been used. Desirable qualities of a tracer gas are detectability, nonreactivity, nontoxicity, neutral buoyancy, relatively low concentration in ambient air, and low cost (Hunt 1980).

All tracer gas measurement techniques are based on a mass balance of the tracer gas in the building. Assuming the outdoor concentration is zero and the indoor air is well mixed, this total balance takes the following form:

$$V\frac{dC}{dt} = F(t) - Q(t)C(t) \tag{16}$$

where

V = volume of space being tested, m^3

Licensed for single user. © 2021 ASHRAE, Inc.

$C(t)$ = tracer gas concentration at time t
dC/dt = time rate of change of concentration, s^{-1}
$F(t)$ = tracer gas injection rate at time t, m^3/s
$Q(t)$ = airflow rate out of building at time t, m^3/s
t = time, s

In Equation (16), density differences between indoor and outdoor air are generally ignored for moderate climates; therefore, Q also refers to the airflow rate into the building. Although Q is often referred to as the infiltration rate, any measurement includes both mechanical and natural ventilation in addition to infiltration. The ratio of Q to the volume V being tested has units of 1/time, often converted to ACH, and is the air change rate I described previously in this chapter.

Equation (16) is based on the assumptions that (1) no unknown tracer gas sources exist, (2) airflow out of the building is the dominant means of removing the tracer gas from the space so the tracer gas does not react chemically in the space and/or is not adsorbed onto or absorbed by interior surfaces or air cleaners, and (3) the tracer gas concentration in the building can be represented by a single value (i.e., the tracer gas is uniformly mixed within the space). In such tracer gas experiments, box-type fans are often operated in rooms to enhance mixing.

Three different tracer gas procedures are used to measure air change rates: (1) decay or growth, (2) constant concentration, and (3) constant injection.

Decay or Growth

Decay. The simplest tracer gas measurement technique is the decay method, also known as the step-down method. A small amount of tracer gas is injected into the space and is allowed to mix with the interior air. After the injection, $F = 0$ and then the solution to Equation (16) is

$$C(t) = C_o e^{-It} \tag{17}$$

where C_o is the concentration of the tracer in the space at $t = 0$.

Equation (17) is generally used to solve for I by measuring the tracer gas concentration periodically during the decay and then fitting the data to the logarithmic form of Equation (17):

$$\ln C(t) = \ln C_o - It \tag{18}$$

Like all tracer gas techniques, the decay method has advantages and disadvantages. One advantage is that, because logarithms of concentration are taken, only relative concentrations are needed, which can simplify calibration of concentration-measuring equipment. Also, the tracer gas injection rate need not be measured, although it must be controlled so that the tracer gas concentrations are within the range of the concentration-measuring device. The concentration-measuring equipment can be located on site, or building samples can be collected in suitable containers (e.g., grab bags) and analyzed elsewhere.

The most serious problem with the decay technique is imperfect mixing of tracer gas with interior air, both at initial injection and during decay. Equations (16) and (17) assume that the tracer gas concentration within the building is uniform at any particular time. If the tracer is not well mixed, this assumption is not appropriate and the determination of I is subject to errors. It is difficult to estimate the magnitude of errors caused by poor mixing, and there has been little analysis of this problem. Sometimes a two-zone model is applied to a room, and a mixing coefficient selected, to estimate the effect of poor mixing [e.g., Rock (1992)].

Growth. The growth or step-up method is similar to the decay method except that the initial tracer gas concentration is low and the injected tracer gas is increased suddenly during the test.

Constant Concentration

In the constant concentration technique, the tracer gas injection rate is adjusted to maintain a constant concentration within the building. If the concentration is truly constant, then Equation (16) reduces to

$$Q(t) = F(t)/C \tag{19}$$

There is less experience with this technique than with the decay procedure, and an increasing number of applications for it exist (Bohac et al. 1985; Collet 1981; Fortmann et al. 1990; Kumar et al. 1979; Walker and Forest 1995; Walker and Wilson 1998; Wilson and Walker 1993).

Because tracer gas injection is continuous, no initial mixing period is required. Another advantage is that tracer gas injection into each zone of the building can be separately controlled; thus, the amount of outdoor air flowing into each zone can be determined. This procedure is best suited for longer-term continuous monitoring of fluctuating infiltration rates. One disadvantage is that it requires measurement of absolute tracer concentrations and injection rates. Also, imperfect mixing of the tracer and interior air causes a delay in the response of the concentration to changes in the injection rate.

Constant Injection

In the constant-injection procedure, the tracer is injected at a constant rate, and the solution to Equation (16) becomes

$$C(t) = (F/Q)(1 - e^{-It}) \tag{20}$$

After sufficient time, the transient term reduces to zero, the concentration attains equilibrium, and Equation (20) reduces to

$$Q = F/C \tag{21}$$

Equation (21) is valid only when air change rate I and airflow rate Q are constant; thus, this technique is only appropriate for systems at or near equilibrium. It is particularly useful in spaces with mechanical ventilation or with high air change rates. Constant injection requires measurement of absolute concentrations and injection rates.

Dietz et al. (1986) used a special case of the constant-injection technique, using permeation tubes as a tracer gas source. The tubes release the tracer at an ideally constant rate into the building being tested, and a sampling tube packed with an adsorbent collects the tracer from the interior air at a constant rate by diffusion. After a sampling period of one week or more, the sampler is removed and analyzed to determine the average tracer gas concentration in the building during the sampling period.

Solving Equation (16) for C and taking the time average gives

$$\langle C \rangle = \langle F/Q \rangle = F\langle 1/Q \rangle \tag{22}$$

where $\langle \ldots \rangle$ denotes time average. Note that the time average of dC/dt is assumed to equal zero.

Equation (22) shows that the average tracer concentration $\langle C \rangle$ and injection rate F can be used to calculate the average of the inverse airflow rate. The average of the inverse is less than the inverse of the actual average, with the magnitude of this difference depending on the distribution of airflow rates during the measurement period. Sherman and Wilson (1986) calculated these differences to be about 20% for one-month averaging periods. Differences greater than 30% have been measured when occupant airing of houses caused large changes in air change rate; errors from 5 to 30% were measured when the variation was caused by weather effects (Bohac et al. 1987). Longer averaging periods and large changes in air change rates during the measurement periods generally lead to larger differences between the average inverse change rate and the inverse of the actual average rate.

Licensed for single user. © 2021 ASHRAE, Inc.

Multizone Air Change Measurement

Equation (16) assumes a single, well-mixed enclosure, and the techniques described are for single-zone measurements. Multizone measurement techniques address airflow between internal zones and between the exterior and individual internal zones (Fortmann et al. 1990; Harrje et al. 1985, 1990; Sherman and Dickerhoff 1989). These techniques are important when considering the transport of pollutants from one room of a building to another. A theoretical development is provided by Sinden (1978a). Multizone measurements typically use either multiple tracer gases for the different zones or the constant-concentration technique. A proper uncertainty analysis is essential in all multizone flow determination (Charlesworth 1988; D'Ottavio et al. 1988).

3. DRIVING MECHANISMS FOR VENTILATION AND INFILTRATION

Natural ventilation and infiltration are driven by pressure differences across the building envelope caused by wind and air density differences. Mechanical air-moving systems also induce pressure differences across the envelope through operation of appliances, such as combustion devices, leaky forced-air thermal distribution systems, and mechanical ventilation systems. The indoor/outdoor pressure difference at a location depends on the magnitude of these driving mechanisms as well as on the characteristics of the openings in the building envelope.

Stack Pressure

Stack pressure is the hydrostatic pressure caused by the weight of a column of air located inside or outside a building. It can also occur within a flow element, such as a duct or chimney that has vertical separation between its inlet and outlet. The hydrostatic pressure in the air depends on density and the height of interest above a reference point.

Air density is a function of local barometric pressure, temperature, and humidity ratio, as described in Chapter 1. As a result, standard conditions should not be used to calculate the density. For example, a building site at 1500 m has air density that is about 20% less than if the building were at sea level. An air temperature increase from –30 to 20°C causes a similar air density difference. Combined, these elevation and temperature effects can reduce air density about 45%. Moisture effects on density are generally much less but can be significant if the change in elevation is great (e.g., in a natural draft cooling tower). Saturated air at 40°C has a density about 5% less than that of dry air at the same pressure.

Assuming the air temperature and humidity ratio are constant over the height of interest, the stack pressure decreases linearly as the distance above the reference point increases. For a single column of air, the stack pressure can be calculated as

$$p_s = p_r - \rho g H \tag{23}$$

where

p_s = stack pressure, Pa
p_r = stack pressure at reference height, Pa
g = gravitational acceleration, 9.81 m/s^2
ρ = indoor or outdoor air density, kg/m^3
H = height above reference plane, m

For tall buildings or when significant temperature stratification occurs indoors, Equation (23) should be modified to include the density gradient over the height of the building.

Temperature, and thus air density differences between indoors and outdoors cause stack pressure differences that drive airflows across the building envelope; the **stack effect** is this buoyancy phenomenon. Sherman (1991) showed that any single-zone building can be treated as an equivalent box from the point of view of stack effect; if there is air leakage, follow the power law as described in the section on Residential Air Leakage. The building is then characterized by an effective stack height and neutral pressure level (NPL) or leakage distribution, as described in the section on Neutral Pressure Level. Once calculated, these parameters can be used in physical, single-zone models to estimate infiltration.

Neglecting vertical density gradients, the stack pressure difference for a horizontal leak at any vertical location is

$$\Delta p_s = (\rho_o - \rho_i) g (H_{\mathrm{NPL}} - H) = \rho_o \left(\frac{T_i - T_o}{T_i} \right) g (H_{\mathrm{NPL}} - H) \tag{24}$$

where

T_o = absolute outdoor temperature, K
T_i = absolute indoor temperature, K
ρ_o = outdoor air density, kg/m^3
ρ_i = indoor air density, kg/m^3
H_{NPL} = height of neutral pressure level above reference plane without any other driving forces, m

Chastain and Colliver (1989) showed that, when there is stratification, the average of the vertical distribution of temperature differences is more appropriate to use in Equation (24) than the localized temperature difference near the opening of interest.

By convention, stack pressure differences are positive when the building is pressurized relative to outdoors, which causes flow out of the building. Therefore, absent other driving forces and assuming no stack effect within the flow elements themselves, when indoor air is warmer than outdoors, the base of the building is depressurized and the top is pressurized relative to outdoors; when indoor air is cooler than outdoors, the reverse is true. At some elevation in the building, with such conditions, the pressure indoors is equal to the outdoors: this height is the neutral pressure level.

Absent other driving forces, the location of the NPL is influenced by leakage distribution over the building exterior and by interior compartmentation. As a result, the NPL is not necessarily at the mid-height of the building; with effective horizontal barriers in tall buildings, it is also possible to have more than one NPL. NPL location and leakage distribution are described in the Combining Driving Forces and Neutral Pressure Level sections.

For a penetration through the building envelope for which (1) there is vertical separation between its inlet and outlet and (2) air inside the flow element is not at the indoor or outdoor temperature (e.g., in a chimney), more complex analyses than Equation (24) are required to determine the stack effect at any location on the building envelope.

Wind Pressure

When wind impinges on and flows around and over a building, it creates a distribution of static pressures on the building's exterior surfaces that depends on the wind direction, wind speed, air density, surface orientation, and surrounding conditions. Wind pressures are generally positive with respect to the static pressure in the undisturbed airstream on the windward side of a building and negative on the leeward sides and roof. However, these pressures depend highly on wind speed, angle, turbulence, the surroundings, and building shape. Static pressures over building surfaces are almost proportional to the velocity pressure of the undisturbed airstream. The wind pressure or velocity pressure is given by the Bernoulli equation, assuming no height change or pressure losses:

$$p_w = C_p \rho \frac{U^2}{2} \tag{25}$$

where

p_w = wind surface pressure relative to outdoor static pressure in undisturbed flow, Pa

Licensed for single user. © 2021 ASHRAE, Inc.

ρ = outdoor air density, kg/m^3 (about 1.2 at or near sea level)
U = wind speed, m/s
C_p = wind surface pressure coefficient, dimensionless

C_p is a function of location on the building envelope and wind direction. Chapter 24 provides additional information on values of C_p.

Most pressure coefficient data are for winds approaching perpendicularly to upwind building surfaces. Unfortunately, for a real building, this fixed wind direction rarely occurs, and when the wind is not normal to the upwind wall, these pressure coefficients do not apply. Walker and Wilson (1994) developed a harmonic trigonometric function to interpolate between the surface average pressure coefficients on a wall that were measured with the wind normal to each of the four building surfaces. This function was developed for low-rise buildings three stories or less in height. For each wall of the building, C_p is given by

$$\begin{aligned} C_p(\phi) = 1/2\{&[C_p(1) + C_p(2)](\cos^2\phi)^{1/4} \\ &+ [C_p(1) - C_p(2)](\cos\phi)^{3/4} \\ &+ [C_p(3) + C_p(4)](\sin^2\phi)^2 \\ &+ [C_p(3) - C_p(4)]\sin\phi\} \end{aligned} \quad (26)$$

where

$C_p(1)$ = pressure coefficient when wind is at 0°
$C_p(2)$ = pressure coefficient when wind is at 180°
$C_p(3)$ = pressure coefficient when wind is at 90°
$C_p(4)$ = pressure coefficient when wind is at 270°
ϕ = wind angle measured clockwise from the normal to wall 1

Because the cosine term in Equation (26) can be negative, its sign must be tracked. When cos(ϕ) is negative, subtract the value of the absolute of cos(ϕ) to the 3/4 power.

The measured data used to develop the harmonic function from Akins et al. (1979) and Wiren (1985) show that typical values for the pressure coefficients are $C_p(1) = 0.6$, $C_p(2) = –0.3$, and $C_p(3) = C_p(4) = –0.65$. Because of geometry effects on flow around a building, application of this interpolation function is limited to low-rise buildings of rectangular plan on flat, featureless sites, with the longest wall less than three times the length of the shortest wall. For less regular buildings or sites, simple correlations are inadequate and building-specific pressure coefficients are required; computational fluid dynamic models are often used. Chapter 24 discusses wind pressures for complex building shapes and for high-rise buildings in more detail.

The wind speed most commonly available for infiltration calculations is that measured at the local weather station, typically the nearest airport. This wind speed needs to be corrected for reductions caused by the difference between the height where the wind speed is measured and the height of the building, and reductions caused by shelter effects.

The reference wind speed used to determine pressure coefficients is usually the wind speed at the eave height for a low-rise building and the building height for a high-rise building. However, meteorological wind speed measurements are made at a different height, typically 10 m for official weather stations, and at a different location than for the buildings of interest. The difference in terrain between the measurement station and the building under study must also be addressed. Chapter 24 shows how to calculate the effective wind speed U_H from the reference wind speed U_{met} using boundary layer theory and estimates of terrain effects.

In addition to the reduction in wind pressures caused by reduced wind speed, the effects of local shelter also act to reduce wind pressures. The shielding effects of trees, shrubbery, and other buildings within several building heights, horizontally, of a particular building produce large-scale turbulence eddies that not only reduce effective wind speed but also alter wind direction. Local geological features or gaps between neighboring large buildings can, at times, greatly increase wind velocity. Thus, meteorological wind speed data must be adjusted carefully when applied to specific buildings and their locations.

Infiltration rates measured by Wilson and Walker (1991) for a row of houses showed reductions in airflow rates of up to a factor of three when the wind changed direction from perpendicular to parallel to the row. They recommended estimating wind shelter for winds perpendicular to each side of the building and then using the interpolation function in Equation (27) to find the wind shelter for intermediate wind angles:

$$\begin{aligned} s = \frac{1}{2}\{&[s(1) + s(2)]\cos^2\phi + [s(1) - s(2)]\cos\phi \\ &+ [s(3) + s(4)]\sin^2\phi + [s(3) - s(4)]\sin\phi\} \end{aligned} \quad (27)$$

where

s = shelter factor for the particular wind direction ϕ
$s(i)$ = shelter factor when wind is normal to wall i (i = 1 to 4, for four sides of a building)

Although this method gives a realistic variation of wind shelter effects with wind direction, estimates for numerical values of wind shelter factor s for each of the four cardinal directions must be provided. Table 8 in the section on Residential Calculation Examples lists typical shelter factors. The wind speed used in Equation (25) is then given by

$$U = sU_H \quad (28)$$

The magnitude of pressure differences found on the surfaces of buildings varies rapidly with time because of turbulent fluctuations in the wind (Etheridge and Nolan 1979; Grimsrud et al. 1979). However, using average wind pressures to calculate pressure differences is usually sufficient to calculate average infiltration values.

Mechanical Systems

Operation of mechanical equipment, such as supply or exhaust systems and vented combustion devices, affects pressure differences across the building envelope and thus air change rates. Interior static pressure adjusts such that the sum of all airflows through openings in the building envelope plus equipment-induced airflows balances to zero. To predict these changes in pressure differences and airflow rates caused by mechanical equipment, the location of each opening in the envelope and relationship between pressure difference and airflow rate for each opening must be known. The interaction between mechanical ventilation system operation and envelope airtightness has been discussed for low-rise buildings (Nylund 1980) and for office buildings (Persily and Grot 1985a; Tamura and Wilson 1966, 1967a).

Air exhausted from a building by a whole-building exhaust system must be balanced by increasing airflow into the building through other openings or the air-handling systems. As pressures vary, air leakage at some locations changes from outflow to inflow. When using makeup air and no dedicated exhaust, the situation is reversed and envelope inflows may become outflows. Thus, the effects of a mechanical system on a building must be considered. Depressurization caused by an improperly designed exhaust system can increase the rate of radon entry into a building and can interfere with proper operation of combustion device venting or other exhaust systems. Pollutant entry can be increased from garages and other attached storage spaces. Depressurization can also force moist outdoor air through the building envelope; for example, during the cooling season in hot, humid climates, moisture may condense in the building envelope and cause rust, rot, or mold. A similar phe-

Licensed for single user. © 2021 ASHRAE, Inc.

nomenon, but in reverse, can occur during the heating, and potentially humidifying, season in cold climates if the building is pressurized. Active pressure control is often recommended, as is proper use of moisture retarders, drainage, and drying of in situ building materials.

The interaction between mechanical systems and the building envelope also pertains to systems serving zones of buildings. Performance of zone-specific exhaust or pressurization systems is affected by leakage in partitions between zones as well as through exterior walls.

Mechanical systems can also create infiltration-driving forces in single-zone buildings. Specifically, some single-family houses with central forced-air duct systems have many distributed supply registers, yet only one central return grille. When insufficiently undercut internal doors are closed in these houses, large positive indoor-to-outdoor pressure differentials are created for rooms with only supply registers, whereas the room or hallway with the return grille tends to depressurize relative to the outdoors. This is caused by the resistance of the internal door undercuts, often partially blocked by carpeting, to flow from the supply register to the return; the magnitudes of the indoor/outdoor pressure differentials created average 3 to 6 Pa (Modera et al. 1991). Balanced airflow systems with ducted air return and distributed grilles or adequately sized transfer grilles (where still allowed by fire code) reduce this effect significantly.

Building envelope airtightness and interzonal airflow resistance can also affect performance of mechanical systems. The actual airflow rate delivered by these systems, particularly ventilation systems, depends on the pressure differences they work against. This effect is the same as the interaction of a fan with its associated ductwork, which is discussed in Chapter 21 of this volume and Chapter 21 of the 2020 *ASHRAE Handbook—HVAC Systems and Equipment*. The building envelope and its leakage should be considered part of the ductwork in determining the pressure drop of the system.

Duct leakage can cause similar problems. Supply leaks to the outdoors tend to depressurize the building; return leaks from the outdoors tend to pressurize it. Keeping these ducts within the conditioned buildings, and sealing all ducts well with durable materials and high-quality construction methods, significantly reduces this problem.

Combining Driving Forces

Pressure differences caused by wind, stack effect, and mechanical systems are considered in combination by adding them together and then determining the resulting airflow rate through each building envelope. The airflows must be determined in this manner, as opposed to adding the airflow rates caused by the separate driving forces, because the airflow rate through each opening is not linearly related to pressure difference.

For uniform indoor air temperatures, the total pressure difference across each leak can be written in terms of a reference wind parameter P_U and stack effect parameter P_T common to all leaks:

$$P_U = \rho_o \frac{U_H^2}{2} \tag{29}$$

$$P_T = g\rho_o[(T_i - T_o)/T_i] \tag{30}$$

where T is absolute air temperature in K.

The pressure difference across each leak, with positive pressures for flow into the building, is then given by

$$\Delta p = s^2 C_p P_U + HP_T + \Delta p_I \tag{31}$$

where Δp_I is the pressure that acts to balance inflows and outflows, including mechanical system flows. Equation (31) can then be applied to every leak for the building with appropriate values of C_p, s, and H. Thus, each leak is defined by its pressure coefficient, shelter, and height. Where indoor pressures are not uniform, more complex and often numerical analyses are required.

Neutral Pressure Level

The neutral pressure level (NPL) varies and is that height or heights in the building envelope where, at that particular instant, there is no indoor-to-outdoor pressure difference. Internal partitions, stairwells, elevator shafts, utility ducts, chimneys, vents, operable windows, and mechanical supply and exhaust systems complicate the prediction of NPL location. An opening with a large area relative to the total building leakage causes the NPL to shift toward the opening. In particular, chimneys and openings at or above roof height raise the NPL in small buildings. Exhaust systems increase the height of the NPL; outdoor air supply systems lower it.

Figure 6 qualitatively shows the addition of driving forces for a building with uniform openings above and below mid-height and without significant internal resistance to airflow. The slopes of the pressure lines are a function of the densities of the indoor and outdoor air. In Figure 6A, with indoor air warmer than outdoor and pressure differences caused solely by thermal forces, the NPL is at mid-height, with inflow through lower openings and outflow through higher openings. For the low air velocities typical in and around buildings, the direction of flow is always from the higher to the lower-pressure region.

Figure 6B presents qualitative uniform pressure differences caused by wind alone, with opposing effects on the windward and leeward sides. When temperature difference and wind effects both exist, the pressures caused by each are added together to determine the total pressure difference across the building envelope. In Figure 6B, there is no NPL because no locations on the building envelope have zero pressure difference. Figure 6C shows the combination, where the wind force of Figure 6B has just balanced the thermal force of Figure 6A, causing no pressure difference at the top windward or bottom leeward side.

The relative importance of wind and stack pressures in a building depends on building height, internal resistance to vertical airflow, location and flow resistance characteristics of envelope openings, local terrain, and the immediate shielding of the building. The taller the building and the smaller its internal resistances to airflow, the stronger the stack effect. The stack effect can be reduced by effectively sealing the building internally between floors, typically by gasketing elevator and stairway doors, and sealing pipe, duct, and electrical penetrations; these measures, when done by code-approved means, also typically reduce undesired smoke migration during fire events. Gasketing interior doors, especially those from exterior spaces or to elevator lobbies, in tall buildings can also help restrict air leakage paths.

The effect of mechanical ventilation on envelope pressure differences is more complex and depends on both the direction of ventilation flow (exhaust or supply) and the differences in these ventilation flows among the zones of the building. If mechanically supplied outdoor air is provided uniformly to each story, the change in the exterior wall pressure difference pattern is uniform. With a nonuniform supply of outdoor air (e.g., to one story only), the extent of pressurization varies from story to story and depends on internal airflow resistance. Pressurizing all levels uniformly has little effect on pressure differences across floors and vertical shaft enclosures, but pressurizing individual stories increases the pressure drop across these internal separations. Pressurizing the ground level is often used in tall buildings in winter to reduce negative air pressures across entries; vestibules and revolving doors are also used to limit air leakage. Vestibules may also be used for elevator lobbies and stair towers to reduce air and smoke movement vertically through tall buildings.

Licensed for single user. © 2021 ASHRAE, Inc.

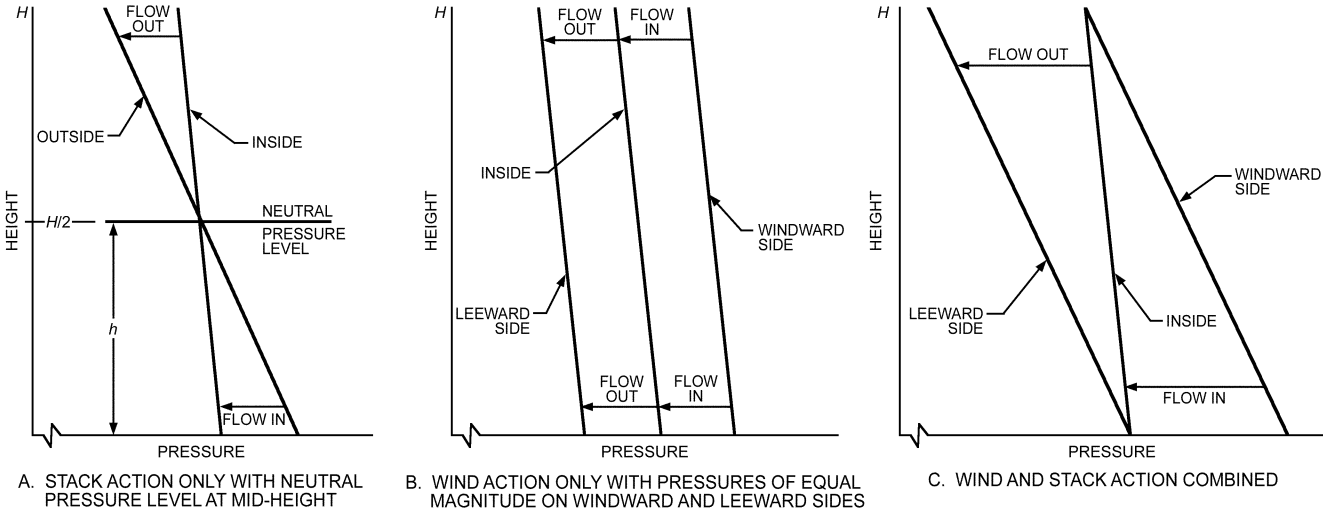

Fig. 6 Distribution of Indoor and Outdoor Pressures over Height of Building

Available data on the NPL in various kinds of buildings are limited. In tall buildings studied by Tamura and Wilson (1966, 1967b), the NPL varied from 0.3 to 0.7 of total building height. For houses, especially those with chimneys, the NPL is usually above midheight. Operating a combustion heat source that vents to the outdoors raises the NPL further, sometimes above the ceiling (Shaw and Brown 1982).

Thermal Draft Coefficient

Compartmentation of a building also affects the NPL location. Equation (24) provides a maximum stack pressure difference, given no internal airflow resistance. The sum of pressure differences across the exterior wall at the bottom and top of the building, as calculated by these equations, equals the total theoretical draft for the building. The sum of actual top and bottom pressure differences, divided by the total theoretical draft pressure difference, equals the **thermal draft coefficient**. The value of the thermal draft coefficient depends on the airflow resistance of exterior walls relative to the airflow resistance between floors. For a building without internal partitions, the total theoretical draft is achieved across the exterior walls (Figure 7A), and the thermal draft coefficient equals 1. In a building with airtight separations between each floor, each story acts independently, its own stack effect being unaffected by that of any other floor (Figure 7B). The theoretical draft is minimized in this case, and each story has its own NPL.

Real multistory buildings are neither open inside, nor airtight between stories. Vertical air passages, stairwells, elevators, and other service shafts allow airflow between floors. Figure 7C represents a heated building with uniform openings in the exterior wall, through each floor, and into the vertical shaft at each story. Between floors, the slope of the line representing the indoor pressure is the same as that shown in Figure 7A, and the discontinuity at each floor (Figure 7B) represents the pressure difference across it. Some of the pressure difference maintains flow through openings in the floors and vertical shafts. As a result, the pressure difference across the exterior wall at any level is less than it would be with no internal flow resistance.

Maintaining airtightness between floors and from floors to vertical shafts is a way to control indoor/outdoor pressure differences because of the stack effect and, therefore, infiltration and exfiltration. Good separation is also conducive to proper operation of mechanical ventilation and smoke management systems. However, care is needed to avoid creating pressure differences that could prevent

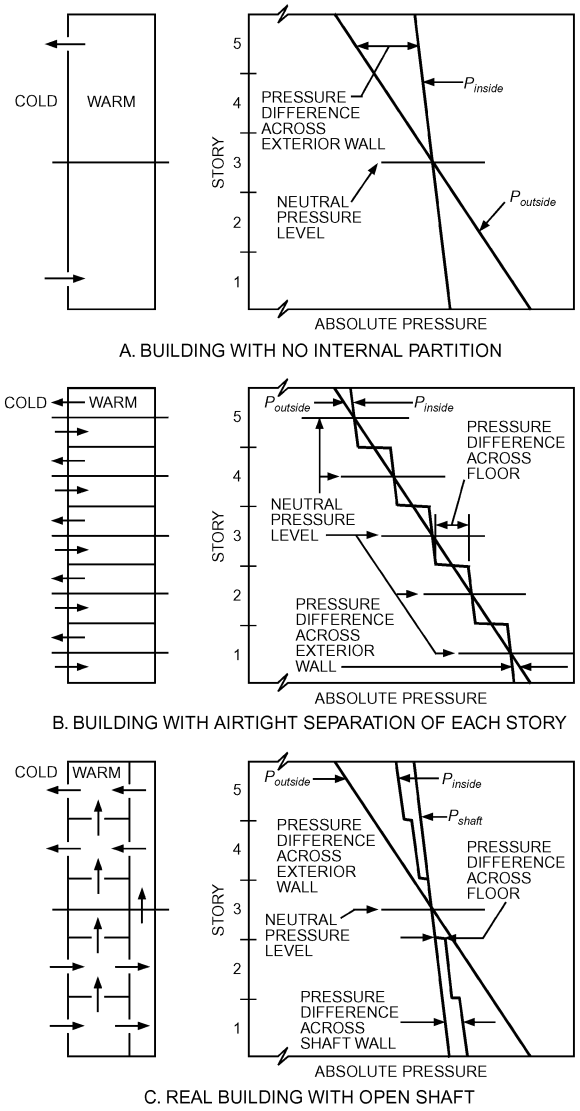

Fig. 7 Compartmentation Effect in Buildings

Licensed for single user. © 2021 ASHRAE, Inc.

egress doors from opening in an emergency. Tamura and Wilson (1967a) showed that when vertical shaft leakage is at least two times envelope leakage, the thermal draft coefficient is almost one and the effect of compartmentation is negligible. Measurements of pressure differences in three tall office buildings by Tamura and Wilson (1967b) indicated that the thermal draft coefficient ranged from 0.8 to 0.9 with ventilation systems off. Modern internal sealing techniques should result in much less vertical leakage.

4. INDOOR AIR QUALITY

Outdoor air requirements for creating and maintaining acceptable indoor air quality (IAQ) have long been debated, and different rationales have produced radically different ventilation standards (Grimsrud and Teichman 1989; Janssen 1989; Klauss et al. 1970; Yaglou et al. 1936; Yaglou and Witheridge 1937). Historically, the major considerations have included the rate of outdoor air admission required to control airborne moisture, carbon dioxide (CO_2), odors, and tobacco smoke generated by occupants. These considerations have led to prescriptions of minimum rates of outdoor air supply per occupant or by unit floor area, or both. More recently, a major concern has been maintaining acceptable indoor concentrations of various additional pollutants that are not generated primarily by occupants. Engineering experience and field studies indicate that an outdoor air supply of about 10 L/s per person is very likely to provide acceptable perceived indoor air quality in office spaces, whereas lower rates may lead to increased sick building syndrome symptoms (Apte et al. 2000; Mendell 1993; Seppanen et al. 1999; Sundell et al. 2011). Information on contaminants can be found in Chapter 11, and odors are addressed in Chapter 12.

Indoor pollutant concentrations depend on the strength of pollutant sources and the total rate of pollutant removal. Pollutant sources include outdoor air; indoor sources such as occupants, furnishings, and appliances; lack of cleanliness as well as use of cleaning and other products; soil adjacent to the building; and building materials themselves, especially when new. Pollutant removal processes include dilution with cleaner outdoor air, local exhaust ventilation, deposition on surfaces, chemical reactions, and air-cleaning processes. If (1) general building ventilation is the only significant pollutant removal process, (2) indoor air is thoroughly mixed, and (3) pollutant source strength and ventilation rate have been stable for a sufficient period, then the steady-state indoor concentration of a specific pollutant is given by

$$C_i = C_o + 10^6 S/Q_{oa} \tag{32}$$

where

C_i = steady-state indoor concentration, ppm
C_o = outdoor concentration, ppm
S = total pollutant source strength, m^3/s
Q_{oa} = ventilation rate, m^3/s

Variation in pollutant source strengths, rather than variation in ventilation rate, is considered the largest cause of building-to-building variation in concentrations of pollutants that are not generated by occupants. Turk et al. (1989) found that a lack of correlation between average indoor respirable particle concentrations and whole-building outdoor ventilation rate indicated that source strength, high outdoor concentrations, building volume, and removal processes are important. Because pollutant source strengths are highly variable, maintaining minimum ventilation rates does not ensure acceptable indoor air quality in all situations. The lack of health-based concentration standards for many indoor air pollutants, primarily because of the lack of health data, makes the specification of minimum ventilation rates difficult.

In cases of high contaminant source strengths, such as with indoor sanding, spray painting, or smoking, impractically high rates of dilution ventilation are required to control contaminant levels, and other methods of control are more effective. Removal or reduction of contaminant sources is the most effective means of control. Controlling a localized source by means of local exhaust, such as paint booths, laboratory fume hoods, range hoods, or bathroom exhaust fans, as well as filtration and absorption, may also be effective [e.g., Rock (2006)].

Some particles can be removed with various types of air filters. Gaseous contaminants with higher relative molecular mass can often be controlled with activated carbon or alumina pellets impregnated with a substance such as potassium permanganate. Chapter 29 of the 2020 *ASHRAE Handbook—HVAC Systems and Equipment* has information on air cleaning.

Protection from Extraordinary Events

The design, operation and maintenance of a building's ventilation system and envelope, as well as other factors, can significantly affect the building's potential vulnerability to extraordinary threats, which range from intentional releases of chemical or biological agents inside or outside a building, to releases of chemicals in industrial or transportation accidents, to natural disasters. ASHRAE (2003) addresses several key steps to manage risk from extraordinary incidents, including

- Evaluate the risk to a facility of an extraordinary incident
- Assess the building's vulnerability
- Determine the degree of acceptable vulnerability
- Consider protective measures or options in relation to new, renovated, and existing buildings

Persily (2004) details how ventilation affects buildings' vulnerability to airborne chemical and biological releases, as well as some strategies for using ventilation, particularly involving airtightness and pressurizing the building interior to protect against outdoor releases, to increase the level of building protection against such incidents. Persily et al. (2007) evaluate retrofit options for protecting buildings from airborne threats; approaches considered include enhanced particle filtration, sorbent-based gaseous air cleaning, ventilation system recommissioning, building envelope airtightening, building pressurization, relocation of outdoor air intakes, shelter-in-place (SIP), isolation of vulnerable spaces such as lobbies, and system shutdown and purge cycles. The filtration and air cleaning options have the advantage of always being operational as long as the systems are properly designed, installed, and maintained. However, the lack of standard test methods is a critical issue in application of some air-cleaning technologies. Building envelope air sealing and pressurization can be quite effective in protecting against outdoor releases as long as effective filtration against the contaminant of concern is also in place. Protection provided by operational changes such as system shutdown and purging depends heavily on timing; if timing is inappropriate, occupant exposure may be increased. Isolating vulnerable zones and other system-related modifications depend on building layout and system design, and careful implementation is necessary for effectiveness under the range of conditions that exist in buildings. Finally, many retrofits can also increase energy efficiency and improve indoor air quality, which should be included in a life-cycle cost comparison of different options to the degree possible. Chapter 60 of the 2019 *ASHRAE Handbook—HVAC Applications* addresses extraordinary events further.

5. THERMAL LOADS

Outdoor air introduced into a building constitutes a large part of the total space-conditioning load, which is one reason to limit air change rates to the minimum required. Air exchange typically represents 20 to 50% of a modern, ventilation-code-compliant building's thermal load in nontemperate climates. The effect on heating

Licensed for single user. © 2021 ASHRAE, Inc.

loads tends to be much larger than on cooling loads (McDowell et al. 2003). Chapters 17 and 18 address thermal loads in more detail.

Air exchange increases a building's thermal load in several ways. First, incoming air must be heated or cooled from the outdoor air temperature to the indoor or supply air temperature. The rate of energy consumption by this sensible heating or cooling is

$$q_s = Q\rho c_p \Delta T \quad (33)$$

where

q_s = sensible heat load, W
Q = airflow rate, m^3/s
ρ = air density, kg/m^3 (about 1.2 at or near sea level)
c_p = specific heat of air, J/(kg·K) (about 1000)
ΔT = temperature difference between indoors and outdoors, K

and at or near sea-level air density, with an adjustment for typical room air humidity, this equation is commonly presented for design use as

$$q_s = 1230Q\Delta t \quad (34)$$

Equations (33) and (34) are known as the **sensible heat equation**. HVAC designers typically assume sea-level air pressure for locations with altitudes of 610 m or lower. A method to adjust for elevation is provided in Chapter 18.

Air exchange also modifies the moisture content of the air in a building. The rate of energy consumption associated with these latent loads, to add or remove water from the air and neglecting the energy associated with any condensate, is

$$q_l = Q\rho\Delta W(2501 + 1.805T) \quad (35)$$

where

q_l = latent heat load, W
ΔW = humidity ratio difference between indoors and outdoors, kg water/kg dry air, kg/kg
T = average of indoor and outdoor temperatures, °C

Equation (35) is known as the **latent heat equation**. When at or near sea level, and for common comfort air temperatures, the right-hand side of Equation (35) is approximately $3.01 \times 10^6\, Q\,\Delta W$.

Example 1. A makeup air unit (MAU) is to condition 2360 L/s of outdoor air in the winter for a building in Atlanta, Georgia. If the air is to be delivered directly to the occupied spaces at 24°C and 30% rh, how much sensible and latent heat must be added to this ventilation air at winter design conditions?

Solution: From the weather data tables provided on the CD included with this volume, Atlanta is at an elevation of about 300 m. Because this is below the rule-of-thumb cutoff of 600 m for assuming sea-level conditions, air density is assumed to be 1.20 kg/m^3. Also from the Atlanta data table, the winter 99% design dry-bulb (db) temperature is –3.1°C, but a mean coincident wet bulb is not provided. However, for humidification design, a dew-point temperature of –12.7°C is given along with its –0.1°C mean coincident dry bulb (MCDB). Using these data, a –17.2°C dew point is assumed as the 99% mean coincident dew point.

From ASHRAE's sea-level psychrometric chart and the winter design conditions, the desired humidity ratio W of the 24°C, 30% rh makeup air is about 0.0056 kg_w/kg_{da}. For the very dry outdoor air, with a dew point of –17.2°C, a problem occurs: the standard sea-level psychrometric chart does not extend below 0°C. Designers often assume that air below this temperature has $W = 0$, and this assumption gives conservative results. However, both high- and low-temperature psychrometric charts are available from ASHRAE, as is a table of moist air properties at standard conditions in Chapter 1. From this table, saturated air at –17.2°C, which is also its dew point, has a humidity ratio of 0.0008298 kg_w/kg_{da}. With 2360 L/s of outdoor air to be conditioned, and using the sensible and latent heat equations for sea level, the energy needed to condition this outdoor air is

$$q_s = 1.23Q\Delta T = 1.23 \times 2360 \text{ L/s}[24 - (-3.1°C)]$$
$$= 78\,666 \text{ W} \approx 78.7 \text{ kW}$$

and

$$q_l = 3010Q\Delta W = 3010 \times 2360 \text{ L/s}(0.0056 - 0.0008298 \text{ kg}_w/\text{kg}_{da})$$
$$= 33\,886 \text{ W} \approx 33.9 \text{ kW}$$

Thus, the MAU's heating coil and humidifier, neglecting fan heat, need to be sized to provide at least a net 78.7 kW of sensible heat, and 33.9 kW of latent heat. Humidification can be provided by cold water, warm water, or steam, so a more precise psychrometric analysis is needed to size the heating coil correctly after the humidification method is selected and it is decided whether the humidifier will be placed before or after the heating coil.

As Example 1 shows, ventilation loads are substantial. They are often 50% or more of the total space conditioning loads in modern, well-insulated, high-occupancy commercial buildings in less temperate climates. When cooling outdoor air, substantial moisture usually must be removed from the ventilation air; reheat or regenerative heat recovery may be required in all but dry climates.

Effect on Envelope Insulation

Air exchange also can affect a building's thermal load by altering performance of the envelope insulation system. Airflow through insulation can decrease the thermal load through heat exchange between infiltrating or exfiltrating air and the insulation. Conversely, air moving in and out of the insulation from the outdoors can increase the thermal load. Experimental and numerical studies demonstrate that significant thermal coupling can occur between air leakage and insulation layers, thereby modifying the heat transmission in building envelopes. In particular, research (Bankvall 1987; Berlad et al. 1978; Lecompte 1987; Wolf 1966) shows that convective airflow through air-permeable insulation in an envelope assembly may degrade its effective thermal resistance. This R-value degradation occurs when outdoor air moves through and/or around the insulation within the wall cavity and returns to the outdoors without reaching the conditioned space. A literature review by Powell et al. (1989) summarized the findings about air movement effects on the effective thermal resistance of porous insulation under various conditions. The effect of such airflow on insulation system performance is difficult to quantify, but should be considered. Airflow within the insulation system can also decrease the system's performance because of moisture condensation in and on the insulation.

Even if air flows only through cracks instead of through the insulation, the actual heating/cooling load from the combined effect of conduction and airflow heat transfer can be lower than the heating/cooling load calculated by Equation (33). This reduction in total heating/cooling load is a consequence of the thermal coupling between conduction and convection heat transfer and is called **infiltration heat recovery (IHR)**. Using a computer simulation, Kohonen et al. (1987) found that the conduction/infiltration thermal interaction reduced total heating load by 15%. Several experimental studies (e.g., Claridge and Bhattacharyya 1990; Claridge et al. 1988; Liu and Claridge 1992a, 1992b, 1992c, 1995; Timusk et al. 1992), using a test cell under both steady-state and dynamic conditions, found that the actual energy attributed to air infiltration can be 20 to 80% of the values given by Equation (35). Judkoff et al. (1997) measured heat recovery in a mobile home under steady-state conditions, and found that up to 40% heat recovery occurs during exfiltration through the envelope. Buchanan and Sherman (2000) performed two- and three-dimensional computational fluid dynamics (CFD) simulations to study the fundamental physics of the IHR process and developed a simple macro-scale mathematical model based on the steady-state one-dimensional convection-diffusion equation to predict a heat recovery factor. Their results show that the traditional method may overpredict the infiltration energy load. Using physical experiments, ASHRAE research project RP-1169 (Ackerman et al. 2006) showed that thermal resistances are affected

Licensed for single user. © 2021 ASHRAE, Inc.

by infiltration and exfiltration, but, on a net basis, the IHR effect can be neglected.

Infiltration Degree-Days

Heating and cooling degree-days (HDDs and CDDs) are a simple way to characterize the severity of a particular climate. Heating and cooling degree-day values are based on sensible temperature data, but infiltration loads are both sensible and latent. **Infiltration degree days (IDDs)** more fully describe a climate and can be used to estimate heat loss or gain from infiltration in residences (Sherman 1986). Total infiltration degree-days is the sum of the heating and cooling infiltration degree-days and is calculated from hour-by-hour weather data and base conditions using weather weighted by infiltration rate. The selection of base conditions is an important part of the calculation of the IDDs. ASHRAE *Standard* 119 lists IDDs for many locations with a particular set of base conditions.

6. NATURAL VENTILATION

Natural ventilation is the flow of outdoor air caused by wind and thermal pressures through intentional openings in a building's shell. Under some circumstances, it can effectively control temperature, contaminants, and possibly airborne moisture in mild climates, but it is not considered practical in hot and humid climates in the summer or in cold climates during the winter. Temperature control by natural ventilation is often the only means of providing some cooling when mechanical air conditioning is not available. The arrangement, location, and control of ventilation openings should combine the driving forces of wind and temperature to achieve a desired ventilation rate and good distribution of ventilation air through the building. However, intentional openings cannot always guarantee adequate temperature and humidity control or indoor air quality because of the dependence on natural wind and stack effects to drive the flow (Wilson and Walker 1992). Using night ventilation and the building's thermal mass effect may be effective for reducing conventional cooling energy consumption in some buildings and climates if moisture condensation can be controlled. Axley (2001a) and the Chartered Institute of Building Services Engineers (CIBSE 2005) reviewed natural ventilation in commercial buildings, including potential advantages and problems, natural ventilation components and system designs, and recommended design and analysis approaches.

Natural Ventilation Openings

Natural ventilation openings include (1) operable windows, clerestories, doors, and skylights; (2) roof ventilators; (3) stacks; and (4) specially designed inlet or outlet openings such as OA louvers and EA grilles, ventilation penthouses or shafts, chimneys, windcatchers, and roof monitors.

Operable windows transmit light, and provide ventilation when opened. They may open by sliding vertically or horizontally; by tilting on horizontal pivots at or near the center; or by swinging on pivots at the top, bottom, or side. The type of pivoting used is important for weather protection and affects airflow rate. Exterior doors, often with insect screens, can also provide a path for natural ventilation; as with operable windows, security concerns must be considered.

Roof ventilators provide a weather-resistant air outlet. Capacity is determined by the ventilator's location on the roof; the resistance to airflow of the ventilator and its ductwork; the ventilator's ability to use kinetic wind energy to induce flow by centrifugal or ejector action; and the height of the draft.

Natural-draft or gravity roof ventilators can be stationary, pivoting, oscillating, or rotating. Selection criteria include appearance, ruggedness, corrosion resistance, stormproofing features, dampers and operating mechanisms, noise, cost, and maintenance. Natural ventilators can be supplemented with power-driven supply or exhaust fans; their motors need only be energized when the natural exhaust capacity is too low. Gravity ventilator dampers can be manual or controlled by thermostat or wind velocity.

A natural-draft roof ventilator should be positioned so that it receives full, unrestricted wind. Turbulence created by surrounding obstructions, including higher adjacent buildings, impairs a ventilator's ejector action. Inlets can be conical or bell-mouthed to increase their flow coefficients. The opening area at any inlet should be increased if screens, grilles, or other structural members cause flow resistance. Building air inlets, most effectively installed at the lowest levels, should be larger than the combined throat areas of all roof ventilators.

Stacks or **vertical flues** should be located where wind can act on them from any direction. Without wind, stack effect alone removes some air from the rooms with inlets. Much practical experience with natural ventilation from before the adoption of modern air-conditioning appears in publications by ASHVE (a predecessor society to ASHRAE).

Ceiling Heights

In buildings that use natural ventilation, floor-to-ceiling heights are often increased well beyond the normal 2.5 to 3.2 m. Higher ceilings, as seen in buildings constructed before air conditioning was available, allow warm air and contaminants to rise above the occupied portions of rooms. Air is then exhausted from the ceiling zones, and outdoor air is introduced near the floors; a degree of floor-to-ceiling displacement airflow is thus desirable when using natural ventilation during the cooling season.

Required Flow for Indoor Temperature Control

The ventilation airflow rate required to remove a given amount of heat from a building can be calculated from Equations (33) and (35) if the quantity of heat to be removed and the indoor/outdoor temperature and humidity ratio differences are known.

Airflow Through Large Intentional Openings

The relationship describing the airflow through a large intentional opening is based on the Bernoulli equation with steady, incompressible flow. The general form that includes stack, wind, and mechanical ventilation pressures across the opening is

$$Q = C_D A \sqrt{2\,\Delta p/\rho} \tag{36}$$

where

Q = airflow rate, m^3/s
C_D = discharge coefficient for opening, dimensionless
A = cross-sectional area of opening, m^2
ρ = air density, kg/m^3
Δp = pressure difference across opening, Pa

The discharge coefficient C_D is a dimensionless number that depends on the geometry of the opening and the Reynolds number of the flow.

Flow Caused by Wind Only

Aspects of wind that affect the ventilation rate include average speed, prevailing direction, seasonal and daily variation in speed and direction, terrain, and local obstructions such as nearby buildings, hills, trees, and shrubbery. Liddament (1988) reviewed the relevance of wind pressure as a driving mechanism. A multiflow path simulation model was developed and used to illustrate the effects of wind on air change rate.

Average wind speeds may be lower in summer than in winter; directional frequency is also a function of season. Natural ventilation systems are often designed for wind speeds of one-half the seasonal average. Equation (37) shows the rate of air forced through

Licensed for single user. © 2021 ASHRAE, Inc.

ventilation inlet openings by wind or determines the proper size of openings to produce given airflow rates:

$$Q = C_v A U \tag{37}$$

where

Q = airflow rate, m^3/s
C_v = effectiveness of openings (C_v is assumed to be 0.5 to 0.6 for perpendicular winds and 0.25 to 0.35 for diagonal winds)
A = free area of inlet openings, m^2
U = wind speed, m/s

Air intakes should be placed in exterior high-pressure regions, and air reliefs should be placed in exterior low-pressure regions, but because of wind variations, these static locations will, at times, not be optimal. Other considerations include flow control when wind speed is high, and security. Air intakes should face directly into the prevailing wind. If they are not advantageously placed, flow will be less than that predicted by Equation (37); if intakes are unusually well placed, flow will be slightly more. Desirable air relief locations are (1) on the leeward side of the building directly opposite the intake; (2) on the roof, in the low-pressure area caused by flow separation; (3) on a side perpendicular to the windward face, where low-pressure areas occur; (4) in a dormer on the leeward side; (5) in roof ventilators; or (6) by stacks. Chapter 24 gives a general description of the wind pressure distribution on a building, but transient computational modeling will likely be required.

Flow Caused by Thermal Forces Only

If building internal resistance is not significant, flow caused by stack effect can be expressed by

$$Q = C_D A \sqrt{2g\,\Delta H_{NPL}(T_i - T_o)/T_i} \tag{38}$$

where

Q = airflow rate, m^3/s
C_D = discharge coefficient for opening
ΔH_{NPL} = height from midpoint of lower opening to NPL, m
T_i = absolute indoor temperature, K
T_o = absolute outdoor temperature, K

Equation (38) applies when $T_i > T_o$. If $T_i < T_o$, replace T_i in the denominator with T_o, and replace $(T_i - T_o)$ in the numerator with $(T_o - T_i)$. If there is thermal stratification, use an average temperature for T_i. If the building has more than one opening for natural ventilation's airflow, the relief and intake areas are considered equal. The discharge coefficient C_D accounts for all viscous effects such as surface drag and interfacial mixing.

Estimating ΔH_{NPL} is difficult for naturally ventilated buildings. If one window or door represents a large fraction (approximately 90%) of the total opening area in the envelope, then the NPL is at the mid-height of that aperture, and ΔH_{NPL} equals one-half the height of the aperture. For this condition, flow through the opening is bidirectional (i.e., air from the warmer side flows through the top of the opening, and air from the colder side flows through the bottom). Interfacial mixing occurs across the counterflow interface, and the orifice coefficient can be calculated by (Kiel and Wilson 1986):

$$C_D = 0.40 + 0.0045|T_i - T_o| \tag{39}$$

If enough other openings are available, airflow through the opening will be unidirectional, and mixing cannot occur. A discharge coefficient of $C_D = 0.65$ should then be used. Additional information on stack-driven airflows for natural ventilation can be found in Foster and Down (1987).

The greatest flow per unit area of openings is obtained when the intake and relief areas are equal; Equations (38) and (39) are based on this equality. Increasing the relief area over intake area (or vice versa) increases airflow but not in proportion to the added area.

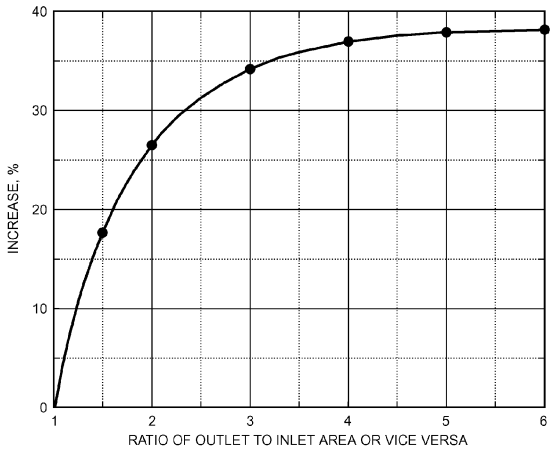

Fig. 8 Increase in Airflow by Increasing Area of One Opening

When openings are unequal, use the smaller area in Equation (38) and add the increase as determined from Figure 8.

Natural Ventilation Guidelines

Several general guidelines should be observed in designing for natural ventilation. Some of these may conflict with other climate-responsive strategies such as using orientation and shading devices to minimize solar gain, with building codes that encourage compartmentalization to restrict fire and smoke movement, or with other design considerations.

System selection

- In hot, humid climates, use mechanical cooling. If mechanical cooling is not available, air velocities should be maximized in the occupied zones of rooms.
- In hot, arid climates, consider evaporative cooling. Airflow throughout the building should be maximized for structural cooling, particularly at night when the outdoor air temperature is low.

Building and surroundings characteristics

- Topography, landscaping, and surrounding buildings should be used to redirect airflow and give maximum exposure to breezes. Vegetation can funnel breezes and avoid wind dams, which reduce the driving pressure differential around the building. Site objects should not obstruct air intakes' openings.
- The building should be shaped to expose maximum shell openings to breezes.
- Architectural elements such as wing walls, parapets, and overhangs should be used to promote airflow into the building interior.
- The long façade of the building and the majority of door and window openings should be oriented with respect to prevailing summer breezes. If there is no prevailing direction, openings should be sufficient to provide ventilation regardless of wind direction.

Opening locations

- Windows should be located in opposing pressure zones. Two openings on opposite sides of a space increase ventilation flow. Openings on perpendicular sides of the building force air to change direction, providing ventilation to a greater area. The benefits of the window arrangement depend on the air relief location relative to the direction of the intake's airstream.
- If a room has only one exterior wall, better airflow is achieved with two widely spaced windows.
- If openings are at the same level and near the ceiling, much of the flow may bypass the occupied portion of a room and be less effective in removing contaminants from there.

Licensed for single user. © 2021 ASHRAE, Inc.

- Vertical distance between openings is required to take advantage of stack effect; the greater the vertical distance, the greater the ventilation rate.
- Openings near the NPL are least effective for thermally induced natural ventilation. If the building has only one large opening, the NPL tends to move to that level, which reduces pressure across the opening.

Opening characteristics

- Greatest airflow per unit area of total opening is obtained by having openings of nearly equal areas. An inlet window smaller than the outlet creates higher inlet velocities. An outlet smaller than the inlet creates lower but more uniform airspeeds through the room.
- Openings with areas much larger than calculated are sometimes desirable when anticipating increased occupancy or very hot weather.
- In one room, horizontally separated windows are generally better than vertically separated windows. They produce more airflow over a wider range of wind directions and are most beneficial in locations where prevailing wind patterns shift.
- Window openings should be accessible to and operable by occupants, unless fully automated. For secondary fire egress, operable windows may be required.
- Intake and exhaust openings should not be obstructed by draperies, furniture, or nearby indoor partitions, for example. Partitions can be placed to split and redirect airflow but should not restrict flow between the building's inlets and outlets. Vertical airshafts or open staircases, where allowable by fire code, can be used to increase and take advantage of stack effects. Enclosed staircases intended for evacuation or safe haven during a fire must not be used for ventilation.

Methods and tools have been developed in recent years to move the art of designing natural ventilation systems beyond the application of simple rules of thumb to engineered design (Axley et al. 2002; CIBSE 2005; Emmerich et al. 2012).

Hybrid Ventilation

Successful application of purely natural ventilation systems for cooling may be very limited in hot or humid climates, such as in much of the United States, by thermal comfort issues and the need for reliability. However, hybrid (or mixed-mode) ventilation systems or operational strategies offer the possibility of saving energy in a greater number of buildings and climates by combining natural ventilation systems with mechanical equipment (Emmerich 2006). The **air-side economizer** is one form of hybrid ventilation control scheme, and enjoys wide use in commercial, industrial, and institutional buildings in appropriate climates. The report of the International Energy Agency's (IEA) Annex 35 describes the principles of hybrid ventilation technologies, control strategies, design and analysis methods, and case studies (Heiselberg 2002). Integrated multizone airflow and thermal modeling is recommended when designing natural and hybrid ventilation systems (Axley 2001a; Dols et al. 2014; Li and Heiselberg 2003).

7. RESIDENTIAL AIR LEAKAGE

Most infiltration in U.S. low-rise residential buildings is dominated by unintentional envelope leakage. However, new construction tends toward tighter building envelopes; where mechanical or natural ventilation is not provided, it is possible for a residence to be too "tight," especially if indoor sources of pollutants are not adequately controlled.

Envelope Leakage Measurement

A building's envelope leakage can be measured with **pressurization testing,** commonly called a **blower-door test**. A fan pressurization test is relatively quick and inexpensive, and it characterizes building envelope airtightness independent of weather conditions; some jurisdictions now mandate that buildings be tested and rated. In this procedure, a large, variable-flow fan or blower is mounted in a door or window and induces a large, roughly uniform pressure difference across the building shell [ASTM *Standards* E779 and E1827; Canadian General Standards Board (CGSB) *Standard* 149.10; ISO *Standard* 9972]. The airflow required to maintain this pressure difference is then measured. The leakier the building is, the more airflow is necessary to induce a specific indoor/outdoor pressure difference. The airflow rate is generally measured at a series of pressure differences ranging from about 10 Pa to 75 Pa. Depressurization tests are also used.

The results of a pressurization test, therefore, consist of several combinations of pressure difference and airflow rate data. An example of typical data is shown in Figure 9. These data points characterize the air leakage of a building and are generally converted to a single value that is reported as the building's airtightness. There are several different measures of airtightness, most of which involve fitting the data to a curve describing the relationship between the airflow Q through an opening in the building envelope and the pressure difference Δp across it. This relationship is called the **leakage function** of the opening. The form of the leakage function depends on the geometry of the opening. Background theoretical material relevant to leakage functions may be found in Chastain et al. (1987), Etheridge (1977), Hopkins and Hansford (1974), Kronvall (1980), and Walker et al. (1997).

Openings in a building envelope are usually not uniform in geometry, and wind varies, so generally flow never becomes fully developed. Each opening in the building envelope, however, is often described by Equation (40), commonly called the **power law equation**:

$$Q = c(\Delta p)^n \tag{40}$$

where

Q = airflow through opening, m^3/s
c = flow coefficient, $m^3/(s \cdot Pa^n)$
n = pressure exponent, dimensionless

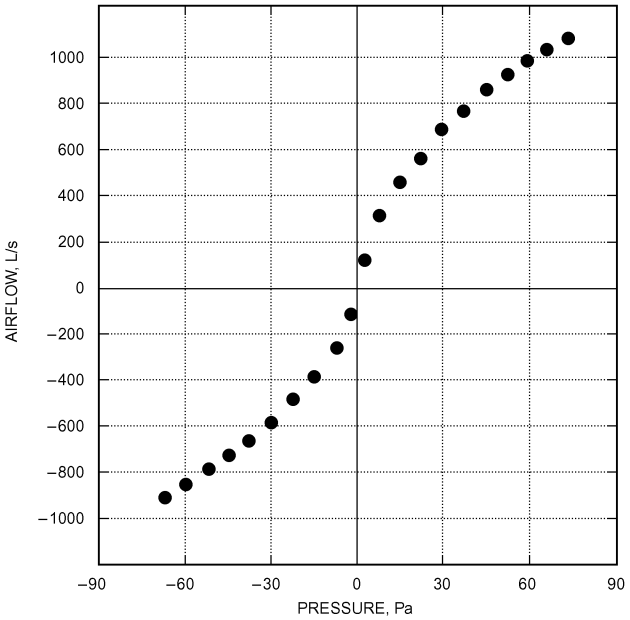

Fig. 9 Airflow Rate Versus Pressure Difference Data from Whole-House Pressurization Test

Licensed for single user. © 2021 ASHRAE, Inc.

Sherman (1992a) showed how the power law can be developed analytically by looking at developing laminar flow in short pipes. Equation (40) only approximates the relationship between Q and Δp. Measurements of single cracks (Honma 1975; Kreith and Eisenstadt 1957) show that n can vary if Δp changes over a wide range. Additional investigation of pressure and flow data for simple cracks by Chastain et al. (1987) indicated the importance of adequately characterizing the three-dimensional geometry of openings and the entrance and exit effects. Walker et al. (1997) showed that, for the arrays of cracks in a building envelope over the range of pressures acting during infiltration, n is constant. A typical value for n is about 0.65. Values for c and n can be determined for a building by using fan pressurization testing.

Airtightness Ratings

In some cases, the predicted airflow rate is converted to an **equivalent** or **effective air leakage area** as follows:

$$A_L = 10\,000\,Q_r \frac{\sqrt{\rho/2\Delta p_r}}{C_D} \tag{41}$$

where

A_L = equivalent or effective air leakage area, cm^2
Q_r = predicted airflow rate at Δp_r (from curve fit to pressurization test data), m^3/s
ρ = air density, kg/m^3
Δp_r = reference pressure difference, Pa
C_D = discharge coefficient

All openings in the building shell are combined into an overall opening area and discharge coefficient for the building when the equivalent or effective air leakage area is calculated. Some users of the leakage area approach set $C_D = 1$. Others set $C_D \approx 0.6$, which is the discharge coefficient for a sharp-edged orifice. The air leakage area of a building is, therefore, the area of an orifice with an assumed value of C_D that would produce the same amount of leakage as the building envelope at the reference pressure.

An airtightness rating, whether based on an air leakage area or a predicted airflow rate, is generally normalized by some factor to account for building size. Normalization factors include floor area, exterior envelope area, and building volume.

With the wide variety of possible approaches to normalization and reference pressure difference, and the use of the air leakage area concept, many different airtightness ratings are used. Reference pressure differences include 4, 10, 25, 50, and 75 Pa. Reference pressure differences of 4 and 10 Pa are advocated by researchers because they are closer to the pressure differences that actually induce air exchange and, therefore, better model the opening's flow characteristics. Although this may be true, they are below the typical range of measured values in the test; therefore, predicted airflow rates at 4 and 10 Pa are subject to significant uncertainty. This uncertainty and its implications for quantifying airtightness are discussed in Chastain (1987), Modera and Wilson (1990), and Persily and Grot (1985b). Round-robin tests by Murphy et al. (1991) to determine the repeatability and reproducibility of fan pressurization devices found that subtle errors in fan calibration or operator technique are greatly exaggerated when extrapolating the pressure versus flow curve down to 4 Pa, with errors as great as ±40%, mainly because of fan and meter calibration errors at low flow.

Some common airtightness ratings include the effective air leakage area at 4 Pa assuming $C_D = 1.0$ (Sherman and Grimsrud 1980); the equivalent air leakage area at 10 Pa assuming $C_D = 0.611$ (CGSB *Standard* 149.10); and the airflow rate at 50 Pa, divided by the building volume to give units of air changes per hour (Blomsterberg and Harrje 1979).

Conversion Between Ratings

Air leakage areas at one reference pressure difference can be converted to air leakage areas at another reference pressure difference by

$$A_{r,2} = A_{r,1}\left(\frac{C_{D,1}}{C_{D,2}}\right)\left(\frac{\Delta p_{r,2}}{\Delta p_{r,1}}\right)^{n-0.5} \tag{42}$$

where

$A_{r,1}$ = air leakage area at reference pressure difference $\Delta p_{r,1}$, cm^2
$A_{r,2}$ = air leakage area at reference pressure difference $\Delta p_{r,2}$, cm^2
$C_{D,1}$ = discharge coefficient used to calculate $A_{r,1}$
$C_{D,2}$ = discharge coefficient used to calculate $A_{r,2}$
n = pressure exponent from Equation (40)

Air leakage area at one reference pressure difference can be converted to airflow rate at some other reference pressure difference by

$$Q_{r,2} = \frac{C_{D,1}A_{r,1}}{10\,000}\sqrt{\frac{2}{\rho}}\,(\Delta p_{r,1})^{0.5-n}(\Delta p_{r,2})^n \tag{43}$$

where $Q_{r,2}$ is airflow rate at reference difference $\Delta p_{r,2}$, in m^3/s.

Flow coefficient c in Equation (40) may be converted to air leakage area by

$$A_L = \frac{10\,000c}{C_D}\sqrt{\frac{\rho}{2}}\,\Delta p_r^{(n-0.5} \tag{44}$$

Finally, air leakage area may be converted to flow coefficient c in Equation (40) with

$$c = \frac{C_D A_L}{10\,000}\sqrt{\frac{2}{\rho}}\,(\Delta p_r)^{0.5-n} \tag{45}$$

Equations (42) to (45) require assumption of a value for n, unless n is reported with the measurement results. When whole-building pressurization test data are fitted to Equation (40), the value of n generally is between 0.6 and 0.7. Therefore, using a value of n in this range is often reasonable.

Building Air Leakage Data

Fan pressurization measures a building's leakage behavior that ideally varies little with time and weather conditions. In reality, unless wind and temperature differences during the measurement period are sufficiently mild, pressure differences induced by weather during the blower door test cause measurement errors. Modera and Wilson (1990) and Persily (1982) studied the effects of wind speed on pressurization test results. Several experimental studies also showed variations of about 20 to 40% over a year in the measured airtightness in the homes studied (Kim and Shaw 1986; Persily 1982; Warren and Webb 1986).

Figure 10 summarizes envelope leakage measured in North American housing (Sherman and Dickerhoff 1998) and from several European and Canadian sources (AIVC 1994). This figure shows the large range of measured envelope tightness but also shows typical and extreme values in the housing stock.

ASHRAE *Standard* 62.2 establishes air leakage performance levels for residential buildings. These levels are in terms of effective annual average infiltration rate Q_{inf}, which is based on normalized leakage area NL:

$$\mathrm{NL} = 0.1\left(\frac{\mathrm{ELA}}{A_{floor}}\right)\left(\frac{H}{H_r}\right)^{0.4} \tag{46}$$

Licensed for single user. © 2021 ASHRAE, Inc.

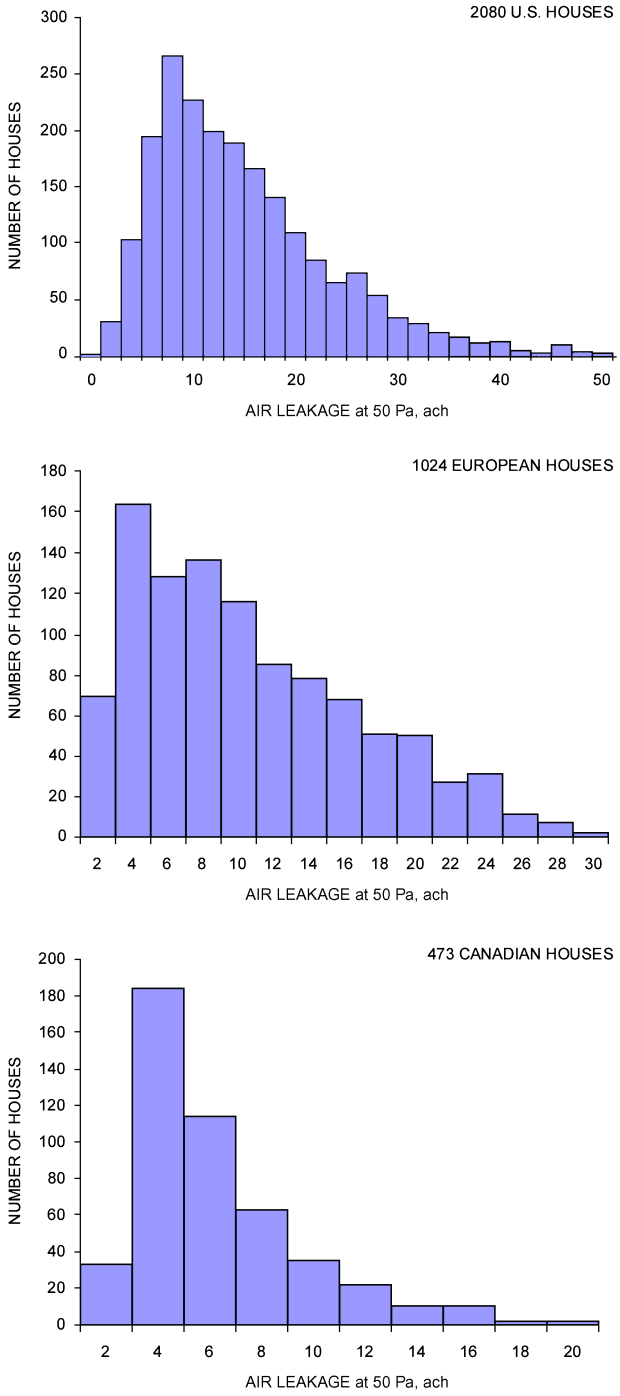

Fig. 10 Envelope Leakage Measurements

where

NL = normalized leakage
H_r = reference height, 2.5 m
H = vertical distance from lowest above-grade floor to highest ceiling, m
ELA = effective leakage area, m^2, using 4 Pa reference pressure

$$ELA = (L_{press} - L_{depress})/2$$

where

L_{press} = leakage area from pressurization, m^2
$L_{depress}$ = leakage area from depressurization, m^2

Air Leakage of Building Components

The fan pressurization procedure discussed in the section on Envelope Leakage Measurement allows whole-building air leakage to be measured. The location and size of individual openings in building envelopes are extremely important because they influence the air infiltration rate of a building as well as the envelope's heat and moisture transfer characteristics. Additional test procedures for pressure-testing individual building components such as windows, walls, and doors are discussed in ASTM *Standards* E283 and E783 for laboratory and field tests, respectively.

Leakage Distribution

Dickerhoff et al. (1982) and Harrje and Born (1982) studied air leakage of individual building components and systems. The following points summarize the percentages of whole-building air leakage area that they found associated with various components and systems. Values in parentheses include the range determined for each component and the mean of the range.

Walls (18 to 50%; 35%). Both interior and exterior walls contribute to the leakage of the structure. Leakage can occur between the sill plate and the floor or foundation; through cracks below the bottom of the gypsum wallboard, around and through electrical boxes, and through plumbing penetrations; and into the attic at the top plates of walls. Holes drilled through the top plates into the attic for passage of wiring are often unsealed.

Ceiling Details (3 to 30%; 18%). Leakage across the top ceiling of the heated space is particularly insidious because it reduces the effectiveness of insulation on the attic floor and contributes to infiltration heat loss. Ceiling leakage also reduces the effectiveness of ceiling insulation in buildings without attics. Recessed lighting, plumbing, and other penetrations leading to the attic are some particular areas of concern, as are intentional openings such as access hatches or for whole-house fans.

Forced-Air Heating and/or Cooling Systems (3 to 28%; 18%). The location of the heating or cooling equipment, air handler, or ductwork in conditioned or unconditioned spaces; the venting arrangement of a fuel-burning device; and the existence and location of a combustion air supply all affect air leakage. Modera et al. (1991) and Robison and Lambert (1989), among others, found that the variability of leakage in ducts passing through unconditioned spaces is high, the coefficient of variation being about 50%. Field studies also showed that in situ repairs can eliminate one-quarter to two-thirds of the observed leakage (Cummings and Tooley 1989; Cummings et al. 1990; Jump et al. 1996; Robison and Lambert 1989). The 18% contribution of ducts to total leakage significantly underestimates their effect because, during system operation, pressure differentials across duct leaks are approximately ten times higher than typical pressure differences across envelope leaks (Modera 1989; Modera et al. 1991) and result in large (factors of two to three), changes in ventilation rate (Cummings et al. 1990; Walker 1999; Walker et al. 1999).

Windows and Doors (6 to 22%; 15%). More variation in window leakage is seen among window types (e.g., casement versus double-hung) than among new windows of the same type from different manufacturers (Weidt et al. 1979). Windows that seal by compressing the weather strip (casements, awnings) often show significantly lower leakage than windows with sliding seals. Leakage around the frames of windows also can be significant if not properly sealed, typically with controlled-expansion foam, during their installation. The door between a residence and an attached garage, or an enclosed hallway in multiunit housing, also needs gasketing to reduce air leakage as well as smoke and other pollutants' movement.

Fireplaces (0 to 30%; 12%). When a fireplace is not in use, poorly fitting dampers allow indoor air to escape. Glass doors may

Licensed for single user. © 2021 ASHRAE, Inc.

not seal the fireplace structure more tightly than a closed damper does. Chimney caps or fireplace plugs (with signs that warn they are in place) effectively reduce leakage through a cold fireplace but may not be allowed by fire code. The gap between a metal fireplace insert and the surrounding wall, tiles, or brick is often another leakage path if not properly sealed.

Exhaust Vents from Conditioned Spaces (2 to 12%; 5%). Exhaust ducts going from conditioned spaces to the outdoors frequently have either no dampers or dampers that do not close properly. The gap between the duct and the wall or roof penetration often needs sealing, as well.

Diffusion Through Walls and Ceilings (<1%). Compared to infiltration through holes and other openings in the structure, diffusion through well-constructed walls and ceilings is not an important flow mechanism. At 5 Pa, the permeability of building materials produces an air change rate of less than 0.01 ach by wall diffusion in a typical house. Proper installation of an air-retarding membrane can help minimize this air leakage path.

Component Leakage Areas. Individual building component leakage areas vary widely from house to house. Typical variability for an individual component is about a factor of 10, depending on the component's construction and installation. Testing should establish the installed leakage of a component in critical applications such as energy-efficient manufactured housing.

Multifamily Building Leakage

Leakage distribution is particularly important in multifamily apartment buildings. These buildings often cannot be treated as single zones because of the internal resistance between apartments. Moreover, leakage between apartments varies widely, from very small for well-constructed buildings with air/moisture retarders and well-sealed wall and floor penetrations between units, to as high as 60% of the total apartment leakage in older, tall apartment buildings of masonry construction (Diamond et al. 1986; Modera et al. 1991). RDH (2013) reviewed the current state of airtightness in multifamily buildings, including testing requirements and techniques, performance targets, and current airtightness levels.

Controlling Air Leakage

New Buildings. It is much easier and more cost-effective to build a tight building than to tighten an existing building. Elmroth and Levin (1983), Eyre and Jennings (1983), Marbek Resource Consultants (1984), and Nelson et al. (1985) provide information and construction details on airtight building design for houses. The economic paybacks for basic "weatherization" improvements are often the most attractive of all energy conservation measures in buildings where no actions have been taken previously.

A continuous **air infiltration retarder**, formerly known as an air barrier, can be an effective way to reduce air leakage through walls, around window and door frames, and at joints between major building elements. Take particular care to ensure its continuity at all wall, floor, and ceiling joints; at window and door frames; and at all penetrations of the retarder such as electrical boxes, plumbing connections, and utility service penetrations. Joints in the **air/vapor retarder** must be lapped and sealed. Plastic vapor retarders installed in the ceiling should be tightly sealed to the vapor retarder in the outer walls and should be continuous over the interior walls. A seal at the top of the interior walls reduces leakage into the attic; the plate on top of the studs generally gives a poor seal. In cold climates, the air infiltration retarder can be installed either on the inside of the wall framing, in which case it usually functions as a vapor retarder as well, or on the outside of the wall framing, in which case it should have a permeance rating high enough to allow diffusion of water vapor from the wall. For a discussion of moisture transfer in building envelopes, see Chapters 25 and 26.

Existing Buildings. Air leakage paths must first be located before the envelope of an existing building can be tightened. As discussed earlier, air leakage into and out of buildings is caused by not only windows and doors but also a wide range of unexpected and unobvious construction defects. Many important leakage routes can be very difficult to find. A variety of techniques developed to locate leakage paths are described in ASTM *Standard* E1186 and Charlesworth (1988).

Once leakages are located, they can be repaired with materials and techniques appropriate to the size and location of the leak. Diamond et al. (1982), Energy Resource Center (1982), Harrje et al. (1979), and many websites and online videos include information on airtightening or "weatherization" in existing residential buildings with caulking, sealing, weatherstripping, and use of door sweeps, for example. With these procedures, air leakage of residential buildings can be reduced dramatically: anywhere from 5% to more than 50%, depending on the extent of the tightening effort and the experience of those doing the work (Blomsterberg and Harrje 1979; Giesbrecht and Proskiw 1986; Harrje and Mills 1980; Jacobson et al. 1986; Verschoor and Collins 1986). Much less information is available for airtightening large, commercial buildings, but the same general principles apply (Parekh et al. 1991; Persily 1991); the joint between corrugated floor or ceiling decking and the exterior walls is often poorly sealed or not at all, and is often hidden from easy view.

8. RESIDENTIAL VENTILATION

Typical infiltration rates in housing in North America vary by an order of magnitude, from tightly constructed housing with seasonal average air change rates as low as 0.1 h^{-1} to loosely constructed housing with air change rates as great as 2.0 h^{-1} or even higher in a few cases. Figures 11 and 12 show histograms of infiltration rates measured in two different samples of North American housing (Grimsrud et al. 1982; Grot and Clark 1979). Figure 11 shows the average seasonal infiltration of 312 houses located in different areas in North America. The median infiltration value of this sample is 0.5 h^{-1}. Figure 12 represents measurements in 266 houses located in 16 U.S. cities. The median value of this sample is 0.9 h^{-1}. The group of houses in the Figure 11 sample is biased toward then-new, then "energy-efficient" houses, whereas the group in Figure 12 represents older, low-income housing. New houses constructed since these studies likely are somewhat tighter because of greater awareness of leakage paths and energy efficiency efforts, including mandated leakage testing in some locations. A modeling study using a set of 209 dwellings that represent 80% of U.S. housing stock estimated a median value of infiltration of 0.44 h^{-1} for all single-family houses, whereas the median for those built since 1990 was 0.26 h^{-1} (Persily et al. 2010).

Additional studies have found average values for houses in regional areas. Palmiter and Brown (1989) and Parker et al. (1990) found a heating season average of 0.40 h^{-1} (range: 0.13 to 1.11 h^{-1}) for 134 houses in Pacific Northwest climates. In a comparison of 292 houses incorporating energy-efficient features, including measures to reduce air infiltration and provide ventilation heat recovery, with 331 control houses, Parker et al. (1990) found an average of about 0.25 h^{-1} (range: 0.02 to 1.63 h^{-1}) for the energy-efficient houses versus 0.49 h^{-1} (range: 0.05 to 1.63 h^{-1}) for the control group. Ek et al. (1990) found an average of 0.5 h^{-1} (range: 0.26 to 1.09 h^{-1}) for 93 double-wide manufactured homes in the Pacific Northwest. Canadian housing stock has been characterized by Riley (1990) and Yuill and Comeau (1989). Although these studies do not represent random samples of North American housing, they indicate the distribution of infiltration rates expected in a group of buildings.

The influence of occupants on infiltration has not been measured directly and varies widely. These influences are, for example,

Licensed for single user. © 2021 ASHRAE, Inc.

operation of doors, windows, and small exhaust fans. Desrochers and Scott (1985) estimated that they add an average of 0.10 to 0.15 h^{-1} to the unoccupied values. Kvisgaard and Collet (1990) found that, in 16 Danish dwellings, occupants on average provided 63% of the total air change rate.

Ventilation air for houses in the United States has traditionally been provided with the assumption occupants will use windows and exhaust fans when needed, and that the building envelope is leaky enough so that infiltration will suffice. Possible difficulties with this approach include occupant error, low infiltration when natural forces (temperature difference and wind) are weak; unnecessary energy consumption when these forces are strong; drafts in cold climates; lack of control of ventilation rates to meet changing needs; poor humidity control; potential for interstitial condensation from exfiltration in cold climates or infiltration in hot humid climates; and lack of opportunity to recover energy used to condition ventilation air. The solution to these concerns is to have a tight building envelope and a properly designed and operated mechanical ventilation system with automatic control.

ASHRAE *Standard* 62.2 and the National Building Code of Canada (NRCC 2010) encourage tighter envelope construction. Hamlin (1991) found a 30% increase in airtightness of tract-built Canadian houses between 1982 and 1989. Also, 82% of newer houses had natural air change rates below 0.3 h^{-1} in March. Yuill (1991) derived a

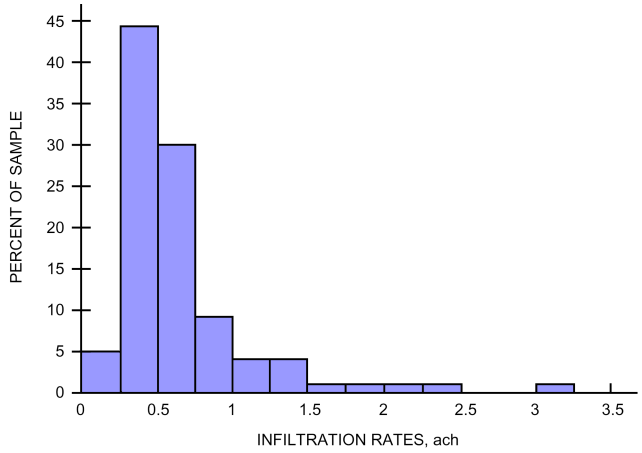

Fig. 11 Histogram of Infiltration Values for Then-New Construction

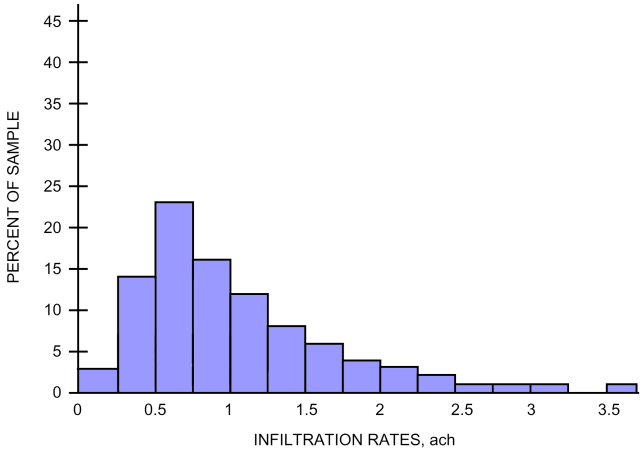

Fig. 12 Histogram of Infiltration Values for Low-Income Housing

procedure to show the extent to which infiltration contributes toward meeting ventilation air requirements. As a result, the National Building Code of Canada has requirements for mechanical ventilation capability in all new dwelling units.

Canadian Standards Association (CSA) *Standard* F326 expands the requirements for residential mechanical ventilation systems to include air distribution within the house, thermal comfort, minimum temperatures for equipment and ductwork, system controls, pressurization and depressurization of the dwelling, installation requirements, and verification of compliance. Verification can be by design or by test, but the total rate of outdoor air delivery must be measured.

Mechanical ventilation is required by ASHRAE *Standard* 62.2 and by building code in some U.S. states; some details of these requirements are described in this chapter. The net benefit of using controlled mechanical ventilation has been demonstrated and studied in various energy-efficient and advanced housing programs (Barley 2001; Palmiter et al. 1991; Riley 1990). Systems can be characterized as local or central; exhaust, supply, or balanced; with forced-air or radiant/hydronic heating/cooling systems; with or without heat recovery; and with continuous operation or with control by occupants, pollutant sensing, timers, or humidity. Note that not all combinations are viable. Various options are described by Fisk et al. (1984), Hekmat et al. (1986), Holton et al. (1997), Lubliner et al. (1997), Palmiter et al. (1991), Reardon and Shaw (1997), Sherman and Matson (1997), Sibbitt and Hamlin (1991), and Yuill et al. (1991).

The simplest systems use bathroom and kitchen fans to exhaust moisture and pollutants outdoors, and to depressurize to augment infiltration. Noise, installed capacity, durability under high or continuous operation, air movement from all rooms (especially bedrooms), envelope moisture, combustion safety, and energy efficiency issues need to be addressed. Many present bath and kitchen fans are ineffective ventilators because of poor installation and design, and many fail to exhaust outdoors. However, properly specified and installed exhaust fans can form part of good whole-house ventilation systems and are so specified in many building codes.

Some systems use their central air-handling unit blower to induce air from the outdoors and distribute it. However, the blower operates intermittently if thermostatically controlled and thus provides little ventilation in mild weather. Continuous blower operation increases energy consumption. If the blower operates continuously when the heat source is off, the combination of lower mixed-air temperature and high air speed can cause cold air drafts when in heating mode. To offset these problems, some systems use variable-speed blowers, which allow operation at lower speeds during mild weather. Others use a timer to cycle the blower when thermostatic demands are inadequate for ventilation purposes (Rudd 1998).

Central exhaust systems use leakage paths and, in some cases, intentional, controllable, and filtered openings in the building envelope for admitting makeup air. Such systems may be suitable for retrofit in existing houses. Energy can be recovered from the exhaust airstream to precondition makeup air or to warm potable water using a heat pump, for example.

For new houses with tightly constructed envelopes, balanced ventilation with passive heat recovery (e.g., air-to-air heat exchangers, heat recovery ventilators) can be appropriate in some climates. Fan-induced, filtered outdoor and exhaust airflow at nearly equal rates through a heat exchanger, where heat and sometimes moisture is transferred between the airstreams. This typically reduces the energy required to condition ventilation air by 60 to 80% (Cutter 1987). Concerns associated with these systems include airflow balance, leakage between streams, biological contamination of wet surfaces, frosting, and initial and maintenance costs.

Air-side economizers, which allow outdoor air to be up to 100% of the supply air at appropriate times, are not typically used in

Licensed for single user. © 2021 ASHRAE, Inc.

small buildings with low internal heat gains relative to the building envelope. Because of heat transfer through building envelopes, these small buildings quickly require heating or cooling as the outdoor air temperature falls or rises. Consequently, from an energy conservation point of view, small envelope-load-dominated buildings do not benefit as much as internal-load-dominated buildings in cool climates from daytime use of air-side economizers; night ventilation of residences during the cooling season may be very attractive, though, when the outdoor humidity ratio is low. Ventilation rates increase dramatically when air-side economizers are in operation, so the extra moisture introduced or removed must be considered.

The type of ventilation system can be selected based on house leakage class as defined in ASHRAE *Standard* 119. Balanced air-to-air systems with heat recovery are optimal for tight houses (leakage classes A to C in the standard). The leakier the house, the larger the contribution from infiltration and the less effective heat recovery ventilation will be. Tightening the envelope beyond the level of ASHRAE *Standard* 62.2 may be warranted in extremely cold climates to better use the heat recovery effect (Sherman and Matson 1997). In mild climates, these systems can also effectively be used in leakage classes D to F. Central exhaust systems should not be used for leakage classes A to C unless special air intakes are provided; otherwise their operation may depressurize the house enough to cause backdrafting through fossil-fueled appliances without closed-combustion systems. Unbalanced systems (either supply or exhaust) are optimal for leakage classes D to F. Ventilation systems are normally not needed for leakage classes G to J, but when they are needed, an unbalanced system is usually the best choice. More discussion of mechanical systems for residences is available in Russell et al. (2005); some information on practices outside North America can be found in McWilliams and Sherman (2005).

Shelter in Place

The most fundamental function of a house is to provide shelter from outdoor conditions. A first response to poor outdoor air quality is to go indoors. Closing windows and other air intakes and turning off exhaust fans reduces air exchange with the outdoors, decreasing the immediate intrusion of outdoor air into the home. However, because no home is perfectly airtight, closing doors and windows does not eliminate intrusion. Because all indoor air ultimately comes from outdoors, indoor air quality eventually comes to dynamic equilibrium with outdoor conditions in an idealized, unoccupied building. The tighter the building, the longer the time needed to come to equilibrium.

The delay time (the time it takes to completely change the air in a building) is determined by the ventilation rate. The effectiveness of sheltering within the home thus depends on envelope tightness. For a home with 0.35 air changes per hour, the delay time is roughly 3 h. For a very tight house without mechanical ventilation, the delay time can easily be twice as long. Most houses in the United States are leakier and thus could have a delay time of about one hour (Sherman and Matson 1997).

Reactive gases in outdoor air, such as ozone, can be decreased to some degree by the building envelope. For other outdoor contaminants, the building envelope serves to delay, not reduce, their introduction into the indoor environment. Such a delay is not very helpful at reducing exposures to outdoor contaminants that persist over days, but can be an effective strategy for short-duration (e.g., less than a few hours) sources. In houses without indoor sources, ozone levels tend to be higher in houses that do not have air conditioners than in those with air conditioners; ozone levels also are higher when windows are open than when they are closed (Weschler 2000). For outdoor exposure times shorter than the delay time, the house serves as a reservoir of cleaner air of that particular pollutant. After the outdoor contaminant is gone, windows can be opened to flush out pollutants that entered or were internally generated during the exposure period.

Safe Havens

Simply going indoors may not be sufficient for highly unusual but potentially lethal events. Chemical spills or fires, explosions, bioterrorism, or similar toxic air pollutant releases can temporarily create dangerous outdoor conditions that render other air quality issues insignificant. With sufficient warning, occupants should leave the vicinity, but the unexpected nature of these events means that the only viable alternative may be to shelter in place.

This strategy may work for short-term releases of airborne toxins. Homes are often too leaky to provide the protection needed for longer-duration events, but individual rooms can be temporarily sealed to become safe havens. A safe haven should be chosen to have as little contact as possible with outer walls, and preferably be on the side of the house farthest downwind from the source. Impermeable tape can be used to seal leaks, cracks, seams, register grilles, and doors, with thick plastic sheeting used to span larger gaps (Sorensen and Vogt 2001). If such a shelter has an air change rate of 0.15 h^{-1} with the house, it can take 4 to 6 h for contaminated outdoor air to affect significantly the safe haven. With very well-sealed, occupied spaces, the air quality inside degrades because of the occupants and materials within, especially rapidly for smaller spaces with higher occupant density. Suffocation is remotely possible, but thermal stress and odor accumulation are more typical.

Where emergencies are somewhat more likely, engineered safe rooms with adequate HVAC systems are needed. In such cases, a safe haven can be designed in advance with thermal conditioning and a highly efficient particle/gas-phase filtration system capable of providing several hours, days, or weeks of protection (Ormerod 1983). A short-term safe haven might be effectively combined with another emergency shelter (e.g., tornado, hurricane, civil defense) to reduce cost.

9. RESIDENTIAL IAQ CONTROL

ASHRAE *Standard* 62.2 presents minimum requirements for residential ventilation air and acceptable indoor air quality, and its user's manual (ASHRAE 2010a) has detailed information for designing and constructing residential buildings in compliance with the standard. Best or good practice may require going beyond the standard's minima. This section describes good practice; however, it presumes that the minimum requirements of 62.2 are met as well.

Traditionally, ventilation air for residences has been provided by natural ventilation controlled by occupants, and also mechanically by increasing infiltration using exhaust fans vented outdoors. Sherman and Matson (1997) showed that many older residential buildings are leaky enough that infiltration alone can meet the minimum requirements of ASHRAE *Standard* 62.2. Houses built or retrofitted to new standards have substantially tighter envelopes and insufficient infiltration under most weather conditions to meet ventilation standards. Studies show that concerns over safety, noise, comfort, air quality, and energy minimize occupants' use of operable windows (Johnson and Long 2005; Price and Sherman 2006). As a result, these houses require supplemental mechanical ventilation to satisfy current standards.

The minimum residential ventilation rate is not always sufficient to adequately dilute all contaminants (e.g., radon), and can introduce undesired substances (e.g., pollen). In these cases, source control, local exhaust, extra ventilation, or more effective air treatment is required to manage contaminant levels. Therefore, especially in single-family dwellings, occupants must be responsible for monitoring and controlling contaminant sources in and around their indoor environments, as well as for operating their dwelling units to meet their individual needs. Increasingly, residences are also used

Licensed for single user. © 2021 ASHRAE, Inc.

for business or hobby purposes, which may introduce air contaminants not addressed in *Standard* 62.2; portions of these residences may require ventilation air as required by *Standard* 62.1 or industrial guidelines.

Source Control

When considering how much whole-house ventilation should be supplied, both typical and unusual sources of indoor pollution should be controlled first to limit the required ventilation rate. This can be done either by mitigating the source itself or by using local exhaust to extract contaminants before they can mix into the indoor environment. Typical sources that should be considered include the following.

Clothes Dryers and Central Vacuum Systems. Clothes dryer exhaust is heavily laden with moisture and laundry by-products such as flammable lint and various gaseous contaminants. Many moisture problems have been traced to clothes dryers vented indoors or to attics, crawlspaces, garages, or other inappropriate locations. Exhaust from clothes dryers, which is typically about 70 L/s, must be vented directly to the outdoors. Similarly, central vacuum systems must be vented directly outdoors to exhaust the finer particles that pass through their filters.

Combustion. Water and carbon dioxide are always produced during combustion of hydrocarbons in air. Dangerous compounds are created, as well. All these products of combustion must be vented directly outdoors, preferably using sealed combustion or direct-vent equipment. Venting must meet or exceed all applicable codes. For buildings with naturally aspirated combustion appliances, excessive depressurization of the building by exhaust systems must be avoided to eliminate backdrafting. Consider a depressurization safety test, such as described in ASTM *Standard* E1998 or CGSB *Standard* 51.71. Fireplace combustion products should be isolated from the occupied space using tight-fitting doors and outdoor air intakes, when necessary. Flues and chimneys must be designed and installed to disperse combustion products well away from air intakes and operable windows, for example. Chapter 35 of the 2020 *ASHRAE Handbook—HVAC Systems and Equipment* has more information on venting systems. Exhaust hoods and fans for ranges and cooktops must vent outdoors.

Carbon monoxide is one of the most unwelcome indoor contaminants, and in significant concentration, poses an imminent threat to life. It can come from virtually any source of combustion, including from motorized vehicles and generators (Emmerich et al. 2013). Even combustion appliances that meet manufacturers' specifications can interact with the building and emit carbon monoxide. At least one carbon monoxide alarm meeting safety standards such as CSA *Standard* 6.19 should be installed near sleeping areas in each dwelling, including each unit of multifamily residential buildings, that has combustion appliances (e.g., fireplaces, stoves, furnaces, water heaters) within the pressure boundary, or has attached garages or storage sheds. Carbon monoxide alarms also should be considered for nonresidential buildings: poisonings have occurred in many building types, including hotels, motels, stores, restaurants, nursing homes, dormitories, laundromats, and schools.

Garages. Garages and storage spaces often contain many sources of contaminants. Doors between them and occupied spaces must be well sealed with gaskets or weatherstripping, including their sills, and possibly be self closing. Depressurized sections of HVAC systems for the regularly occupied portions of residences, such as the systems' air handlers or return or intake ducts, should not be located in garages. If such sections must pass through garages, they must be well sealed and never have registers or grilles installed in the garages or storage spaces; if such spaces need conditioning, they must use their own isolated systems. Take care to ensure that there is a good pressure barrier between the garage and the occupied space, typically using an air/moisture retarder such as heavy polyethylene as well as excellent sealing of the door between. Carbon monoxide sources may be present in garages, so pressure barriers, fire-rated compartmentation, and ventilation of attached residences are life-safety measures. Separate ventilation systems that slightly depressurize attached garages and storage spaces and that exhaust directly outdoors should be considered, especially when these support spaces are tightly constructed or are in cold climates. Several studies (Batterman et al. 2006; Emmerich et al. 2003; Fugler 2004) of contaminant sources and transport in garages found that, in some cases, significant fractions of infiltration air enter houses from attached garages, and that modern residential garages are tighter than older garages to reduce energy consumption and to improve comfort; garages were previously assumed to be leaky enough to avoid many related IAQ problems.

Particulates. The ventilation system should be designed such that return and any outdoor air is well filtered before passing through the thermal conditioning components of the HVAC system. Pressure drops associated with this filtration must be considered in the design and installation of the air-handling system. Particulate filters or air cleaners should have a minimum efficiency of 60% for 3 μm particles, which is equivalent to a MERV 6 designated filter according to ASHRAE *Standard* 52.2.

Microbiologicals. Because ventilation can increase the source as well as removal rates of various air pollutants, it is, at best, moderately effective at reducing exposures to many airborne microbiologicals. Ventilation can, however, be part of the moisture balance that is critical to retarding fungal growth on surfaces and spores released into the air, depending on indoor and outdoor conditions.

Radon and Other Soil Gases. Buildings are exposed to gases and water that migrate through the soil into occupied spaces through cracks or other leaks. Soil gases vary with time and conditions, and can contain toxins from pesticides, landfills, fuels, or sewers, but the highest-profile pollutant in this category is radon and its radioactive-decay-produced "daughters." Source control measures, such as differential pressure control and ground-to-building airtightening, are far more effective than ventilation mechanisms at controlling exposure to soil gas in buildings. See Chapter 11 for more information.

Volatile Organic Compounds (VOCs). VOCs are ubiquitous in modern life. Examples of products that emit VOCs include manufactured wood products, paints, stains, varnishes, solvents, pesticides, adhesives, wood preservatives, waxes, polishes, cleansers, lubricants, sealants, dyes, air fresheners, fuels, plastics, copy machines, printers, tobacco products, perfumes, cooking by-products, and dry-cleaned clothes. Whenever possible, VOCs and other toxic compounds should be stored outside the occupied space in loosely constructed or ventilated enclosures such as garden sheds or detached garages, and away from occupied buildings' ventilation intakes and operable windows. When unusual amounts of such compounds are present, consider using additional ventilation should be considered (e.g., extra ventilation during and for a while after construction projects). Reduced-VOC-emitting products are often available.

Outdoor Air. Outdoor air may at times contain unacceptably high levels of pollutants, including ozone, pollen, carbon monoxide, particulate matter, odors, or toxic agents. At such times, it may be impossible to provide acceptable indoor air quality using solely outdoor air, and increased ventilation rates can actually decrease indoor air quality. In locations where this problem may be anticipated, provide automatic or manual controls to allow temporary reduction of the ventilation rate. If these events are frequent, consider a means to more effectively clean recirculated air during these times.

Local Exhaust

After source elimination, the single most important source control mechanism in dwellings is local exhaust. Kitchens, utility

Licensed for single user. © 2021 ASHRAE, Inc.

rooms, bathrooms, and other spaces designed to allow specific contaminant releases should be provided with local exhaust that is vented to the outdoors. Workshops, recreation rooms, smoking areas, art studios, greenhouses, and hobby rooms may also require local ventilation and/or air cleaning to remove contaminants generated by the activities involved. Contaminants of concern should be evaluated to determine how much additional ventilation is required. Many of these rooms can be adequately ventilated by following the requirements for kitchens or bathrooms. If unvented combustion appliances must be used, rooms with these appliances should also meet general ventilation requirements for kitchens, because such appliances generate significant amounts of moisture and, often, ultrafine particles, even when operating properly.

Mechanical exhaust (i.e., a fan with ducting to the outdoors) with adequate makeup air is the preferred method for providing local ventilation. Normally, such an exhaust system is designed to operate intermittently under manual control to send contaminated air outdoors when occupants recognize the need for ventilation. However, in many circumstances, a continuous, lower-flow-rate exhaust can work as well. Specific provisions for intermittent versus continuous exhaust rates are typically included in ventilation standards such as ASHRAE *Standard* 62.2; some example information is provided here.

Continuous Local Mechanical Exhaust. A continuously operating mechanical exhaust system is intended to operate without occupant intervention. This exhaust may be part of a balanced whole-building mechanical ventilation system. The system should be designed to operate during all hours in which the dwelling is occupied. Override control, to provide higher exhaust rates when needed, should be provided. The minimum delivered ventilation should be at least that given in Table 1.

Intermittent Local Mechanical Exhaust. An intermittently operating local mechanical exhaust is intended to be operated as needed by the occupant. Shutoff timers, occupancy controls, multiple-speed fans, and switching integral with room lighting are helpful, provided they do not impede occupant control. The minimum airflow rate should be at least that given in Table 2.

Alternatives. Cleaning recirculated air can sometimes be substituted for local exhaust, if it can be shown to be effective and reliable in removing contaminants of concern. Natural ventilation is not generally a suitable method for local exhaust and ventilation air needs in many climates and spaces. Using natural ventilation can cause reentrainment problems when contaminated exhaust or exfiltrating air reenters the building. In milder climates, natural ventilation may be acceptable when the contaminant of concern is related to odor rather than health or safety. Purpose-designed passive exhaust systems have shown acceptable ventilation in some European settings, and may be considered in lieu of mechanical systems. Axley (2001b) discusses evaluation and design of passive residential ventilation systems further.

Whole-House Ventilation

Although control of significant sources of pollution in a dwelling is important, whole-house ventilation through centrally introduced, conditioned, and distributed outdoor air may still be needed. Each dwelling should be provided with outdoor air according to code adopted by the local jurisdiction; general guidance according to ASHRAE *Standard* 62.2 is given in Table 3 of this chapter. The rate is the sum of the Area-Based and Occupancy-Based columns. Design occupancy expectations in the United States can be based on the number of bedrooms as follows: first bedroom, two persons; each additional bedroom, one person. Additional ventilation should be considered when occupant densities exceed one person per 25 m^3.

Natural whole-house ventilation that relies on occupant operation should not be used to make up any part of the minimum total whole-house ventilation air requirement. However, because occupancy and sources vary significantly, the capacity to ventilate above minimum rates can be provided by operable exterior openings such as doors and windows.

Table 1 Continuous Exhaust Airflow Rates

Application	Airflow Rate	Notes
Enclosed kitchen	5 ach	Based on kitchen volume
Restroom	10 L/s	Not less than 2 ach

Table 2 Intermittent Exhaust Airflow Rates

Application	Airflow Rate	Notes
Kitchen	50 L/s	With a vented range hood
	150 L/s	With other exhaust fans, including downdraft
Restroom	25 L/s	Not less than 2 ach

Table 3 Total Ventilation Air Requirements

Area Based	Occupancy Based
0.15 L/s per square metre of floor space	3.5 L/s per person, based on normal occupancy

Air Distribution

Ventilation air should be provided to each habitable room through mechanical and natural air distribution. If a room does not have a balance between air supply and return or exhaust, pathways for transfer air should be provided. These pathways may be door undercuts, transfer ducts with grilles, or simply grilles where ducts are not necessary; however, building codes must be checked, because compartmentation requirements for limiting fire and smoke movement may restrict transfer air means or require rated fire and smoke dampers, for example.

In houses without central air handlers, special provisions to distribute outdoor air may be required. Rooms in which occupants spend many continuous hours, such as bedrooms, may require special consideration. Local and whole-house ventilation equipment should be chosen to be energy efficient, easy to maintain, reliable, durable, and quiet. Consider using heat recovery, especially in cold climates.

Selection Principles for Residential Ventilation Systems

Occupant comfort, energy efficiency, ease of use, service life, initial and life-cycle costs, value-added features, and indoor environmental quality should be considered when selecting a strategy and system. Poorly designed, installed, or maintained HVAC and related systems can be potential contributors to poor indoor air quality. For example, occupants may not use the ventilation systems as intended if operation results in thermal or acoustical discomfort or excessive energy use. The resulting lack of ventilation might produce poor indoor air quality. Therefore, careful design, construction, commissioning, operation, and maintenance is necessary to provide optimum effectiveness.

All exhaust, supply, or air handler fans have the potential to change the pressure of an indoor space relative to the outdoors. High-flow fans, such as in the air handler and with some cooking exhausts, can cause significant depressurization, particularly in tightly constructed homes. Considering these effects is essential in design. Excessive depressurization of the living space relative to outdoors may cause backdrafting of combustion appliances and increased migration of contaminants such as radon or other soil gases, car exhaust, or insulation particles into the living space. Depressurization can also result in increased moisture intrusion into building cavities in warm, moist climates and may cause more structural damage and fungal growth. Pressurization of the living space can cause condensation in building cavities in cold climates, also resulting in structural damage. Excess pressure can best be prevented by balancing

Licensed for single user. © 2021 ASHRAE, Inc.

ventilation and exhaust systems and tightly sealing duct systems. In addition, adequate pathways must be available for all return air to the air-handling devices.

Occupant activities, operation of exhaust fans, and leaky ducts may depressurize the structure. Options to address backdrafting concerns include

- Using combustion appliances with sealed combustion systems
- Locating combustion appliances in a ventilated room isolated from depressurized zones by well-sealed partitions
- Providing supply or makeup air to balance exhaust from the zone
- Testing to ensure that depressurization is not excessive

The system must also be designed, built, operated, and maintained in a way that discourages growth of biological contaminants. Typical precautions include sloping condensate drain pans toward the drain, keeping condensate drains free of obstructions, keeping cooling coils free of dirt and other obstructions, maintaining humidifiers, and checking for and eliminating any cause of moisture inside ducts. Additional information on residential ventilation system design and IAQ control may be found in ASHRAE *Guideline* 24.

10. SIMPLIFIED MODELS OF RESIDENTIAL VENTILATION AND INFILTRATION

This section describes several calculation procedures, ranging from simple estimation techniques to more physical models. Orme (1999) provides a more thorough review of simplified models. For energy modeling or code compliance, a particular building's air change rate cannot be reliably deduced from the building's construction or age, or from a simple visual inspection. Some measurement is necessary, such as a pressurization test of envelope airtightness or a detailed quantification of the leakage sites and their magnitude. The air change rate of a building may be calculated given (1) the location and leakage function for every opening in the building envelope and between major building zones, (2) the wind pressure coefficients over the building envelope, and (3) any mechanical ventilation airflow rates. These data are generally unavailable for all except very simple structures or extremely well studied buildings. Therefore, their values must be assumed. The appropriateness of these assumptions influences the accuracy of predictions of air change rates.

Empirical Models

These models of residential infiltration are based on statistical fits of infiltration rate data for specific houses. They use pressurization test results to account for house airtightness and take the form of simple relations between infiltration rate, an airtightness rating, and, in most cases, weather conditions. Empirical models account for envelope infiltration only and do not include intentional ventilation. In one approach, the calculated air change rate at 50 Pa based on a pressurization test is simply divided by a constant approximately equal to 20 (Sherman 1987). This technique does not account for the effect of infiltration-driving mechanisms on air exchange. Empirical models that do account for weather effects have been developed by Kronvall (1980), Reeves et al. (1979), and Shaw (1981).

The latter two models account for building air leakage using the values of c and n from Equation (40). The only other data required are wind speed and temperature difference. These empirical models predict long-term (one-week) infiltration rates very well in the houses from which they were developed; they do not, however, work as well in other houses because of the building-specific nature of leakage distribution, wind pressure, and internal partitioning. Persily (1986) and Persily and Linteris (1983) compared measured and predicted house infiltration rates for these and other models. The average long-term differences between measurements and predictions are generally about 40%, although individual predictions can be inaccurate by 100% or more (Persily 1986; Walker and Wilson 1998).

Multizone Models

Multicell models of airflow in buildings treat buildings as a series of interconnected zones and assume that air within each zone is well mixed. Several such models have been developed by Allard and Herrlin (1989), Etheridge and Alexander (1980), Feustel and Raynor-Hoosen (1990), Herrlin (1985), Liddament and Allen (1983), Walton (1984, 1989), and Walton and Dols (2003). They are all based on a mass balance for each zone of the building. These mass balances are used to solve for interior static pressures in the building by requiring that inflows and outflows for each zone balance to zero. The user must provide information describing building envelope leakage, values to account for wind pressure on the building envelope, temperatures for each zone, and any mechanical ventilation airflow rates. Wind pressure coefficient data in the literature, air leakage measurement results from the building or its components, and air leakage data from research can be used as estimates. These models not only solve for whole-building and individual zone air change rates, but also determine airflow rates and pressure differences between zones. These interzone airflow rates are useful for predicting pollutant transport within buildings with well mixed zones. Chapter 13 has more details on multizone airflow and IAQ modeling.

Single-Zone Models

Several procedures have been developed to calculate building air change rates that are based on physical models of the building interior as a single zone. These single-zone models are only appropriate for buildings with minimal internal resistance to airflow, and are therefore inappropriate for large, multizone buildings. Some models of this type have been developed by Cole et al. (1980), Sherman and Grims-rud (1980), Walker and Wilson (1998), and Warren and Webb (1980). The section on Residential Calculation Examples uses both basic and enhanced models (Bradley 1993; CHBA 1994; Hamlin and Pushka 1994; Palmiter and Bond 1994; Walker and Wilson 1998).

The **basic model** uses effective air leakage area A_L at 4 Pa, which can be obtained from a whole-building pressurization test. The **enhanced model** uses pressurization test results to characterize house air leakage through leakage coefficient c and pressure exponent n. The enhanced model improves on the basic model by using a power law to represent envelope leakage, including a flue as a separate leakage path, and having separate wind effects for houses with crawlspaces or basements instead of slab-on-grade foundations.

For both models, the user must provide the wind speed, the temperature difference, information on the distribution of leakage over the building envelope, a wind shelter parameter or local shielding for the basic model, and a terrain coefficient. The predictive accuracy of the enhanced model can be very good, typically ±10% when parameters are well known for the building in question (Palmiter and Bond 1994; Sherman and Modera 1986; Walker and Wilson 1998). All models' results are sensitive to the user-provided data, and some of these parameters are often quite difficult to determine.

Superposition of Wind and Stack Effects

Simplified physical models of infiltration solve the problem of two natural driving forces (wind and stack) separately and then combine them in a process called **superposition**. Superposition is necessary because each physical process can affect internal and external air pressures on the building's envelope, and can cause interactions between physical processes that are otherwise independent. An exact

Licensed for single user. © 2021 ASHRAE, Inc.

solution is impossible, because (1) detailed properties of all the building leaks are unknown and (2) leakage is a nonlinear process. Therefore, most modelers have developed a simplified superposition process to combine stack and wind effects. Sherman (1992b) compared various superposition procedures and derived a generalized superposition equation involving simple leakage distribution parameters, and showed that the result is always subadditive. Typically, only 35% of infiltration from the smaller effect can be added to the larger effect. Depending on the specific building and conditions, that percentage could go as high as 85% or as low as zero. Walker and Wilson (1993) compared several superposition techniques to measured data. Sherman, as well as Walker and Wilson, found quadrature, shown in Equation (47), to be a robust superposition technique:

$$Q = \sqrt{Q_s^2 + Q_w^2} \tag{47}$$

The following sections discuss how superposition is combined with calculation of wind and stack flows to determine total flow.

Residential Calculation Examples

Basic Model. The following calculations are based on the Sherman and Grimsrud (1980) model, which uses the effective air leakage area at 4 Pa. This leakage area can be obtained from a whole-building pressurization test. Using effective air leakage area, the airflow rate from infiltration is

$$Q = \frac{A_L}{1000}\sqrt{C_s|\Delta T| + C_w U^2} \tag{48}$$

where

Q = airflow rate, m^3/s
A_L = effective air leakage area, cm^2
C_s = stack coefficient, $(L/s)^2/(cm^4 \cdot K)$
ΔT = average indoor-outdoor temperature difference for time interval of calculation, K
C_w = wind coefficient, $(L/s)^2/[cm^4 \cdot (m/s)^2]$
U = average wind speed measured at local weather station for time interval of calculation, m/s

Table 4 shows values of C_s for one-, two-, and three-story houses. The value of wind coefficient C_w depends on the local shelter class of the building (Table 5) and the building height. Table 6 shows values of C_w for one-, two-, and three-story houses in shelter classes 1 to 5. In calculating values in Tables 4 and 6, the following assumptions were made:

- Terrain used for converting meteorological to local wind speeds is that of a rural area with scattered obstacles
- $R = 0.5$ (half the building leakage in the walls)
- $X = 0$ (equal amounts of leakage in the floor and ceiling)
- Heights of one-, two-, and three-story buildings = 2.5, 5.0, and 7.5 m, respectively

Table 4 Basic Model Stack Coefficient C_s

	House Height (Stories)		
	One	Two	Three
Stack coefficient	0.000 145	0.000 290	0.000 435

Table 5 Local Shelter Classes

Shelter Class	Description
1	No obstructions or local shielding
2	Typical shelter for an isolated rural house
3	Typical shelter caused by other buildings across street from building under study
4	Typical shelter for urban buildings on larger lots where sheltering obstacles are more than one building height away
5	Typical shelter produced by buildings or other structures immediately adjacent (closer than one house height: e.g., neighboring houses on same side of street, trees, bushes)

Example 2. Estimate the infiltration at winter design conditions for a two-story house in Lincoln, Nebraska. The house has effective air leakage area of 500 cm^2 and volume of 340 m^3, and the predominant wind is perpendicular to the street (shelter class 3). The indoor air temperature is 20°C.

Solution: The 99% design temperature for Lincoln is –19°C. Assume a design wind speed of 6.7 m/s. From Equation (48), with $C_s = 0.000\ 290$ from Table 4 and $C_w = 0.000\ 231$ from Table 6, the airflow rate caused by infiltration is

$$Q = \frac{500}{1000}\sqrt{(0.000\ 290 \times 39) + (0.000\ 231 \times 6.7^2)}$$
$$= 0.0736\ m^3/s = 265\ m^3/h$$

From Equation (2), air change rate I is equal to Q divided by the building volume:

$$I = (265\ m^3/h)/340\ m^3 = 0.78\ h^{-1} = 0.78\ ach$$

Example 3. Predict the average infiltration during a one-week period in January for a one-story house in Portland, Oregon. During this period, the average indoor/outdoor temperature difference is 17 K, and average wind speed is 2.7 m/s. The house has volume of 255 m^3 and effective air leakage area of 690 cm^2, and it is located in an area with buildings and trees within 10 m in most directions (shelter class 4).

Solution: From Equation (48), the airflow rate caused by infiltration is

$$Q = \frac{690}{1000}\sqrt{(0.000\ 145 \times 17) + (0.000\ 104 \times 2.7^2)}$$
$$= 0.0392\ m^3/s = 141\ m^3/h$$

The air change rate is therefore

$$I = 141/255 = 0.55\ h^{-1} = 0.55\ ach$$

Example 4. Estimate the average infiltration over the heating season in a two-story house with volume of 310 m^3 and leakage area of 848 cm^2. The house is located on a lot with several large trees but no other close buildings (shelter class 3). Average wind speed during the heating season is 3.2 m/s, and the average indoor/outdoor temperature difference is 20 K.

Solution: From Equation (48), the airflow rate from infiltration is

$$Q = \frac{848}{1000}\sqrt{(0.000\ 290 \times 20) + (0.000\ 231 \times 3.2^2)}$$
$$= 0.077\ m^3/s = 276\ m^3/h$$

The average air change rate is therefore

$$I = 276/310 = 0.89\ h^{-1} = 0.89\ ach$$

Enhanced Model. This section presents a simple, single-zone approach to calculating air infiltration rates in houses based on the Walker and Wilson (1998) model. The airflow rate from stack and wind infiltration is

$$Q_s = c C_s \Delta T^n \tag{49}$$
$$Q_w = c C_w (sU)^{2n} \tag{50}$$

where

Q_s = stack airflow rate, m^3/s

Table 6 Basic Model Wind Coefficient C_w

Shelter Class	House Height (Stories)		
	One	Two	Three
1	0.000 319	0.000 420	0.000 494
2	0.000 246	0.000 325	0.000 382
3	0.000 174	0.000 231	0.000 271
4	0.000 104	0.000 137	0.000 161
5	0.000 032	0.000 042	0.000 049

Licensed for single user. © 2021 ASHRAE, Inc.

Q_w = wind airflow rate, m^3/s
c = flow coefficient, $m^3/(s \cdot Pa^n)$
C_s = stack coefficient, $(Pa/K)^n$
C_w = wind coefficient, $(Pa \cdot s^2/m^2)^n$
s = shelter factor
ΔT = indoor – outdoor temperature difference, K
n = pressure exponent

In calculating tabulated values of C_s, C_w, and s, the assumptions were

- Each story is 2.5 m high.
- The flue is 15 cm in diameter and reaches 2 m above the upper ceiling.
- The flue is unsheltered.
- Half of envelope leakage (not including the flue) is in the walls and one-quarter each is at the floor and ceiling, respectively.
- $n = 0.67$

The following examples use typical values for terrain factors, house height, and wind speed measurement height, wind speed multiplier G given in Table 7, and use a relationship based on equations found in Chapter 24.

Example 5. Estimate the infiltration at winter design conditions for a two-story slab-on-grade house with a flue in Lincoln, Nebraska. The house has a flow coefficient of $c = 0.051$ $m^3/(s \cdot Pa^n)$ and a pressure exponent of $n = 0.67$ (corresponding to effective leakage area of 500 cm^2 at 4 Pa). The building volume is 340 m^3. The 97.5% design temperature is –19°C, and design wind speed is 6.7 m/s.

Solution: For a slab-on-grade two-story house with a flue, Table 8 gives $C_s = 0.089$ $(Pa/K)^n$ and $C_w = 0.156$ $(Pa \cdot s^2/m^2)^n$. The house is maintained at 20°C indoors. The building wind speed is determined by taking the design wind speed U_{met} and applying by the wind speed multiplier G from Table 7:

$$U = GU_{met} = 0.59(6.7) = 3.95 \text{ m/s}$$

From Table 5, the shelter class for a typical urban house is 4. Table 9 gives the shelter factor for a two-story house with a flue and shelter class 4 as $s = 0.64$. The stack flow is calculated using Equation (49):

$$Q_s = (0.051)(0.089)[20 - (-19)]^{0.67} = 0.053 \text{ m}^3/\text{s}$$

The wind flow is calculated using Equation (50):

$$Q_w = (0.051)(0.156)(0.64 \times 3.95)^{1.34} = 0.027 \text{ m}^3/\text{s}$$

Substituting Q_s and Q_w into Equation (47) gives $Q = 0.059$ m^3/s = 214 m^3/h. From Equation (2), air change rate I is equal to Q divided by the building volume:

$$I = (214 \text{ m}^3/\text{h})/340 \text{ m}^3 = 0.63 \text{ h}^{-1} = 0.63 \text{ ach}$$

Table 7 Enhanced Model Wind Speed Multiplier *G*

	House Height (Stories)		
	One	Two	Three
Wind speed multiplier G	0.48	0.59	0.67

Table 8 Enhanced Model Stack and Wind Coefficients

	One Story		Two Story		Three Story	
	No Flue	With Flue	No Flue	With Flue	No Flue	With Flue
C_s	0.054	0.069	0.078	0.089	0.098	0.107
C_w for slab-on-grade	0.156	0.142	0.170	0.156	0.170	0.167
C_w for crawlspace	0.128	0.128	0.142	0.142	0.151	0.154

Table 9 Enhanced Model Shelter Factor *s*

Shelter Class	No Flue	One Story with Flue	Two Story with Flue	Three Story with Flue
1	1.00	1.10	1.07	1.06
2	0.90	1.02	0.98	0.97
3	0.70	0.86	0.81	0.79
4	0.50	0.70	0.64	0.61
5	0.30	0.54	0.47	0.43

Example 6. Estimate the average infiltration over a one-week cold-weather period for a single-story house with a crawlspace in Redmond, Washington. The house has a flow coefficient of $c = 0.078$ $m^3/(s \cdot Pa^n)$ and a pressure exponent of $n = 0.6$ (corresponding to effective leakage area of 690 cm^2 at 4 Pa). The building volume is 255 m^3. During this period, the average indoor-to-outdoor temperature difference is 16 K, and wind speed is 2.7 m/s. The house is electrically heated and has no flue.

Solution: For a single-story house with no flue, $C_s = 0.054$ $(Pa/K)^n$. For a crawlspace, $C_w = 0.128$ $(Pa \cdot s^2/m^2)^n$. From Table 7, for a one-story house, $G = 0.48$.

$$U = GU_{met} = 0.48(2.7) = 1.3 \text{ m/s}$$

Table 9 gives shelter factor $s = 0.50$ for a house with no flue and shelter class 4. Stack flow is calculated using Equation (49):

$$Q_s = (0.078)(0.054)(16)^{0.6} = 0.022 \text{ m}^3/\text{s}$$

Wind flow is calculated using Equation (50):

$$Q_w = (0.078)(0.128)(0.50 \times 1.3)^{1.34} = 0.006 \text{ m}^3/\text{s}$$

Substituting Q_s and Q_w into Equation (47) gives $Q = 0.023$ m^3/s = 83 m^3/h. From Equation (2), air change rate I is equal to Q divided by the building volume:

$$I = (83 \text{ m}^3/\text{h})/(255 \text{ m}^3) = 0.32 \text{ h}^{-1} = 0.32 \text{ ach}$$

Example 7. Estimate the infiltration for a three-story house in San Francisco, California. The house has a flow coefficient of $c = 0.102$ $m^3/(s \cdot Pa^n)$ and a pressure exponent of $n = 0.67$ (corresponding to effective leakage area of 1000 cm^2 at 4 Pa). The building volume is 395 m^3. The indoor/outdoor temperature difference is 5 K and wind speed is 4.47 m/s. The house has a flue and a crawlspace.

Solution: For a three-story house with a flue, $C_s = 0.107(Pa/K)^n$. For a crawlspace, $C_w = 0.154$ $(Pa \cdot s^2/m^2)^n$. From Table 7, for a three-story house, $G = 0.67$.

$$U = GU_{met} = 0.67(4.47) = 3.0 \text{ m/s}$$

The prevailing wind blows along the row of houses parallel to the street, so the house has a shelter class of 5. Table 9 gives the shelter factor for a three-story house with a flue and shelter class 5 as $s = 0.43$.

$$Q_s = (0.102)(0.107)(5)^{0.67} = 0.032 \text{ m}^3/\text{s}$$

$$Q_w = (0.102)(0.154)(0.43 \times 3.0)^{1.34} = 0.022 \text{ m}^3/\text{s}$$

Substituting Q_s and Q_w in Equation (47) gives $Q = 0.039$ m^3/s = 140 m^3/h. The air changes per hour are

$$I = (140 \text{ m}^3/\text{h})/(395 \text{ m}^3) = 0.35 \text{ h}^{-1} = 0.35 \text{ ach}$$

Combining Residential Infiltration and Mechanical Ventilation

Significant infiltration and mechanical ventilation often occur simultaneously in residences. The pressure difference from Equation (31) can be used for each building leak, and the flow network (including mechanical ventilation) for the building can be solved to find the airflow through all the leaks while accounting for the effect of the mechanical ventilation. However, for simplified models, natural infiltration and mechanical ventilation are usually determined

Licensed for single user. © 2021 ASHRAE, Inc.

separately and require a superposition method to combine the flow rates.

Sherman (1992b) compared various procedures and derived a generalized superposition equation that involves simple leakage distribution parameters. The result is always subadditive. For small, unbalanced fans, typically only half the mechanically introduced outdoor airflow contributes to the total, but this fraction can be anywhere between 0 and 100%, depending on leakage distribution. When the makeup air fan's flow rate is large, infiltration may be ignored, because the building becomes either neutrally or positively pressurized.

In special cases when the leakage distribution is known and highly skewed, it may be necessary to work through the superposition method in more detail. For example, in a wind-dominated situation, a makeup air fan has a much bigger effect than an exhaust fan on changing the total ventilation rate; the same is true for houses with high neutral pressure levels in cold climates. For the general case, when details are not known or can be assumed to be broad and typical, the following superposition gives good results:

$$Q_{comb} = Q_{bal} + \sqrt{Q_{unbal}^2 + Q_{infiltration}^2} \quad (51)$$

Typical Practice

The preceding sections on estimating infiltration in low-rise residences represent current analytical techniques typically used for research and remediation purposes, but most small residential buildings are designed and constructed without direct involvement of ventilation engineers. Contractors, who typically prepare these buildings' designs, are required to follow mandates in various codes and standards, and they apply experience-based rules of thumb when determining, for example, exhaust needs. Often, leaky buildings or air quality problems result. Research and experience have shown that tightening building envelopes and using mechanical ventilation with heat recovery can improve indoor air quality and reduce energy consumption. Retaining the services of a ventilation engineer before construction begins is advisable in some situations.

11. COMMERCIAL AND INSTITUTIONAL AIR LEAKAGE

Envelope Leakage

ASTM *Standard* E779 and CGSB *Standard* 149.10 include methods to measure the airtightness of building envelopes of single-zone buildings. Although many multizone buildings can be treated as single-zone buildings for testing by opening interior doors or by inducing equal pressures in adjacent zones, these standards provide no guidelines for dealing with problems arising in tall buildings, such as stack and wind effects. Tall buildings require refinement and extensions of established procedures because they have obstacles to accurate measurement not present in small buildings, including large envelope leakage area, interfloor leakage, vertical shafts, and large wind and stack pressures. Chapter 4 in the 2019 *ASHRAE Handbook—HVAC Applications* discusses tall buildings and their challenges in detail.

For conducting a pressurization test in a large building, the building's own air-handling equipment sometimes can be used to induce test pressures, as described in CGSB *Standard* 149.15. In other cases, a large fan is brought to the building to perform the test, as described by CIBSE *Standard* TM23. ASHRAE RP-1478's final report (Anis and Brennan 2014) discusses how to test the envelope leakage of large commercial buildings.

In the past, building envelopes of large commercial buildings were often assumed to be quite airtight. Tamura and Shaw (1976a) found that, assuming a flow exponent n of 0.65 in Equation (40), air leakage measurements in eight Canadian office buildings with sealed windows ranged from 610 to 2440 $cm^3/(s \cdot m^2)$. Persily and Grot (1986) performed whole-building pressurization tests in large office buildings that showed that pressurization airflow rate divided by building volume was relatively low compared to that of houses. However, if these airflow rates are normalized by building envelope area instead of by volume, the results indicate envelope airtightness levels similar to those in typical North American houses. The same study also looked at eight U.S. office buildings and found air leakage ranging from 1080 to 5220 $cm^3/(s \cdot m^2)$ at 75 Pa. This means that the office buildings' envelopes were leakier than expected. Typical air leakage values per unit wall area at 75 Pa were 500, 1500, and 3000 $cm^3/(s \cdot m^2)$ for tight, average, and leaky walls, respectively (Tamura and Shaw 1976a).

Emmerich and Persily (2014) summarized available measured airtightness data for almost 400 buildings, including about 70 constructed between 2000 and 2010. The average air leakage for the buildings was 20% tighter than the average for the 228 buildings included in a similar 2011 analysis. The data were analyzed to determine factors that affect airtightness (e.g., building type, height). Recent additions to the database, previously reported by Emmerich and Persily (2005), include numerous buildings constructed to meet the specifications of sustainable building programs such as U.S. Green Building Council's LEED® rating system, as well as buildings designed and constructed with air retarders. The overall average airtightness reported was 13.1 $m^3/(h \cdot m^2)$ for six-sided (i.e., including slabs and basement surfaces) envelope surface areas at 75 Pa. The data show only weak trends related to year of construction, height, floor area, wall construction, or building type, but do demonstrate that buildings designed and constructed with attention to airtightness are much tighter than typical commercial buildings. The analysis found that the 79 buildings with air retarders had an average air leakage almost 70% less than the average for the 290 buildings not specified as having air retarders, thus demonstrating the critical need to design and construct commercial buildings with dedicated air retarders to support sustainable building design. However, the wide variation among the measures taken to limit or reduce air leakage among these buildings and the lack of detailed descriptions of the air retarders make it difficult to predict a specific level of airtightness that will result from use of a specific air retarder approach.

In the United States, commercial building construction practices are addressed by various standards, codes, and green building program requirements, and Table 10 summarizes some of the relevant air leakage limits from these requirements. Both ASHRAE *Standards* 90.1 and 189.1 require **continuous air barriers (CABs)** for most commercial buildings. Since 2010, *Standard* 90.1 requires the CAB to meet either a material tightness limit [0.02 $L/(s \cdot m^2)$ under a pressure differential of 75 Pa] or an assembly tightness limit [0.2 $L/(s \cdot m^2)$ under a pressure differential of 75 Pa], but it does not include a whole-building tightness limit or a requirement for whole-building pressurization testing. The building commissioning requirements of *Standard* 189.1-2014 include a whole-building test demonstrating the building meets a tightness limit of 1.25 $L/(s \cdot m^2)$ under a pressure differential of 75 Pa or the implementation of a rigorous envelope commissioning program.

The 2012 International Energy Conservation Code® (IECC®) (ICC 2012a) has requirements with options for a CAB with material or assembly tightness or a whole-building test. The 2012 International Green Construction Code® (IgCC®) (ICC 2012b) includes the same requirements as the 2012 IECC but also includes a whole-building testing requirement consistent with the U.S. Army Corps of Engineers (USACE 2009) value. Many U.S. state building codes currently or will include requirements for continuous air barriers either through reference to IECC, IGCC, ASHRAE *Standard* 90.1 or 189.1, or their own independent requirements; a current list of requirements is available at www.airbarrier.org.

Since 2009, the USACE has required that conditioned buildings be built or retrofitted to include a continuous air barrier to control air leakage through the building envelope (USACE 2009). The

GSA = U.S. General Services Administration
*Whole-building limits are based on six-sided enclosure, including slab and below-grade walls.

specification requires whole-building testing with a maximum leakage of 1.25 L/(s·m²) at 75 Pa based on the six-sided building enclosure area (including slab and subgrade walls). The average tightness for a set of 285 new and retrofitted USACE buildings was reported to be 0.9 L/(s·m²) (Zhivov 2013). Also, the U.S. General Services Administration (GSA 2010) since 2010 requires all new U.S. federal buildings for the Public Buildings Service to include an air barrier with the whole building having an air leakage rate of not more than 2.0 L/(s·m²) at 75 Pa.

Grot and Persily (1986) also found that eight recently constructed office buildings had infiltration rates ranging from 0.1 to 0.6 ach when outdoor air intakes were deactivated. Infiltration rates exhibited varying degrees of weather dependence, generally much lower than that measured in houses. Infiltration in commercial buildings can have many negative consequences, including reduced thermal comfort, interference with proper operation of mechanical ventilation systems, degraded indoor air quality, moisture damage of building envelope components, and increased energy consumption. These results suggest strongly that commercial buildings' envelopes require tighter construction, and that continuous air barrier systems should be used in the enclosures of all conditioned buildings. Since 1997, the Building Environment and Thermal Envelope Council of the National Institute of Building Sciences has sponsored several symposia on air barriers for buildings in North American climates. Others have also published articles on the importance of limiting air leakage in commercial buildings (Anis 2001; Ask 2003; Fennell and Haehnel 2005).

Envelope leakage in commercial buildings also depends on HVAC system operation. Often, commercial buildings and their HVAC systems are in operation during normal daytime business hours but switch into "unoccupied" operation at nights and on weekends and holidays. If pressurized while their HVAC systems operate, infiltration is often very low or even eliminated in buildings with tight envelopes. However, in unoccupied mode, this pressurization is often lost, so infiltration and potentially moisture intrusion may be significant at times.

Air Leakage Through Internal Partitions

In large buildings, air leakage associated with internal partitions becomes very important. Walls, doors, floors, ceilings, plenums, chases, transfer ducts and grilles, and elevator and stairway enclosures are the major separations of concern in these buildings. Their leakage characteristics are needed in multizone models to predict infiltration through exterior walls and airflow patterns in a building. These internal resistances are also important in the event of a fire to predict smoke movement patterns and evaluate smoke management systems.

Table 11 gives air leakage areas calculated at 75 Pa with $C_D = 0.65$ for different internal partitions of commercial buildings (Klote et al. 2012). Figure 13 presents examples of measured air leakage rates of

Table 11 Air Leakage Areas for Internal Partitions in Commercial Buildings (at 75 Pa and $C_D = 0.65$)

Construction Element	Wall Tightness	Area Ratio
		A_L/A_w
Stairwell walls	Tight	0.14×10^{-4}
	Average	0.11×10^{-3}
	Loose	0.35×10^{-3}
Elevator shaft walls	Tight	0.18×10^{-3}
	Average	0.84×10^{-3}
	Loose	0.18×10^{-2}
		A_L/A_f
Floors	Average	0.52×10^{-4}

A_L = air leakage area A_w = wall area A_f = floor area

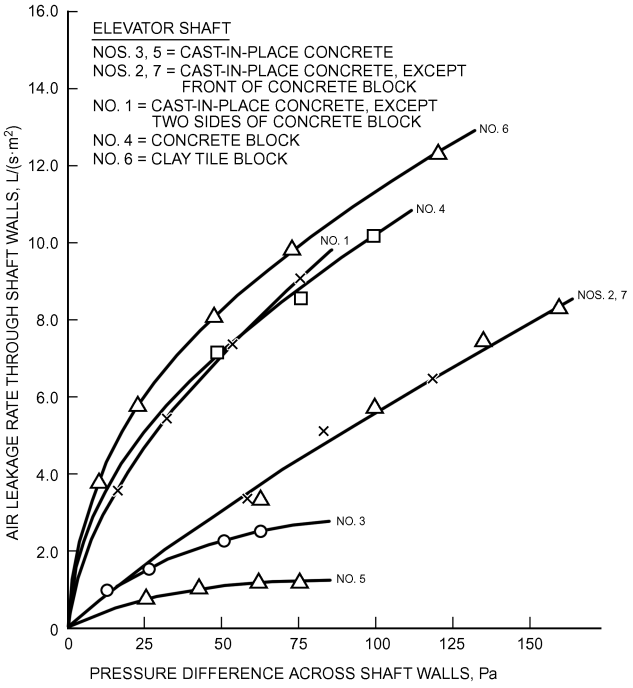

Fig. 13 Air Leakage Rates of Elevator Shaft Walls

elevator shaft walls (Tamura and Shaw 1976b), the type of data used to derive the values in Table 11. Consult Chapter 54 of the 2019 *ASHRAE Handbook—HVAC Applications* for performance models and applications of smoke control systems. As with the exterior shell, making significant effort to seal unintentional openings in internal partitions in large buildings can improve thermal comfort and energy efficiency, as well as improve the building's performance in a fire.

Leakage paths, intentional or otherwise, at the top of elevator shafts are often equivalent to orifice areas of 0.4 to 1.0 m². Air leakage rates through stair tower and elevator doors are shown in Figure 14 as a function of average crack width around the door. Sealing elevator and stair doors well, and possibly using indoor vestibules for them, can reduce air as well as smoke flow rates significantly. Air leakage areas associated with other openings in commercial buildings are also important for air movement calculations. These include interior doors and partitions, suspended ceilings in buildings where space above the ceiling is used for air supply or return, and other components of the air distribution system.

Air Leakage Through Exterior Doors

Door infiltration depends on the type and use of door, room, and building, and on air speed and pressure differentials. In residences

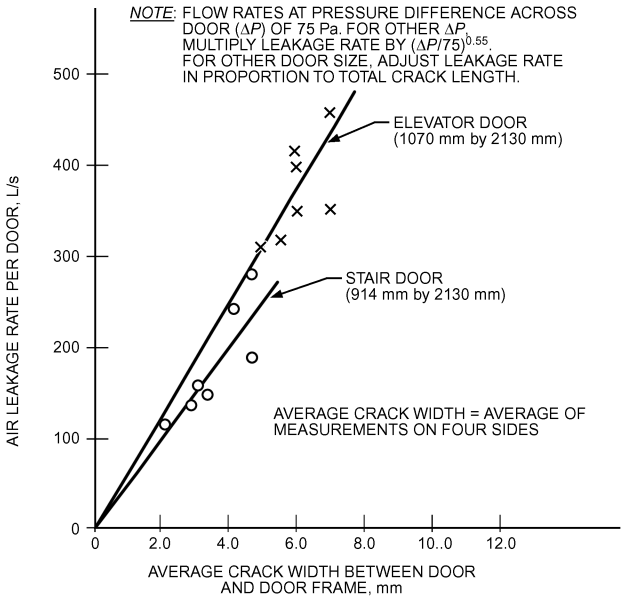

Fig. 14 Air Leakage Rate of Door Versus Average Crack Width

and small buildings where doors are used infrequently, a closed door is assumed, and air exchange can be estimated based on air leakage through cracks between door, frame, and sill. Where exterior door are used frequently, airflow through them increases significantly as door-opening frequency increases. Consider using vestibules or revolving doors for high-frequency applications.

Air Leakage Through Automatic Doors

Automatically swinging, sliding, rotating, or overhead doors are a major source of air leakage. They are normally installed where large numbers of people use the doors or where bulk goods or vehicles are transported through the doorways. These doors stay open longer with each use than manually operated doors. Air leakage through an automatic door can be reduced by installing a vestibule. However, pairs of automatic doors on the inside and outside of a vestibule normally have overlapping open periods, even when used by only one person at a time. Therefore, it is important that designers include airflow through automatic doors when calculating heating and cooling loads in adjacent spaces.

To calculate the average airflow rate through an automatic door, the designer must consider the area of the door, the pressure difference across it, the discharge coefficient of the door when it is open, and the fraction of time that it is open. Obtaining the discharge coefficient is complicated by the fact that it changes as the door opens and closes.

To simplify this calculation, ASHRAE research project RP-763 (Yuill 1996) developed Figure 15 to combine the discharge coefficients of doors as they open and close with the fraction of time that doors are open at a particular level of use. This figure presents an overall airflow coefficient as a function of the number of people using a door per hour. To obtain the average infiltration rate through an automatic door, multiply this coefficient by the door's opening area and by the square root of the pressure difference between the outdoor and indoor air at the door's location. The pressure difference across a door in a building is difficult to predict accurately and depends on wind pressure on the building, stack effect caused by the indoor/outdoor temperature difference, and effects of air-handling system operation. It also depends on leakage characteristics of the building's exterior walls and of internal partitions.

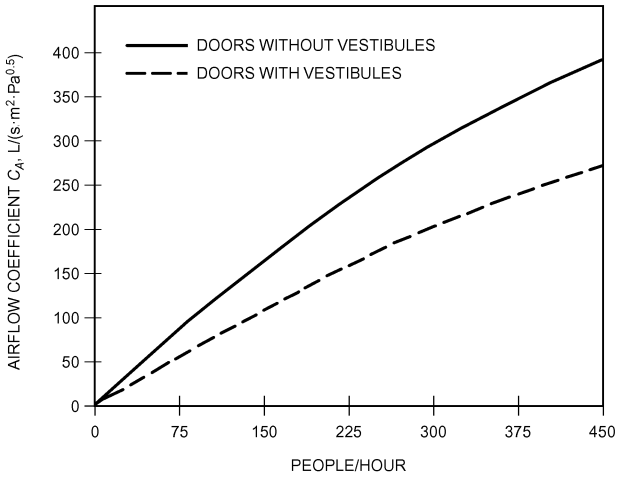

Fig. 15 Airflow Coefficient for Automatic Doors

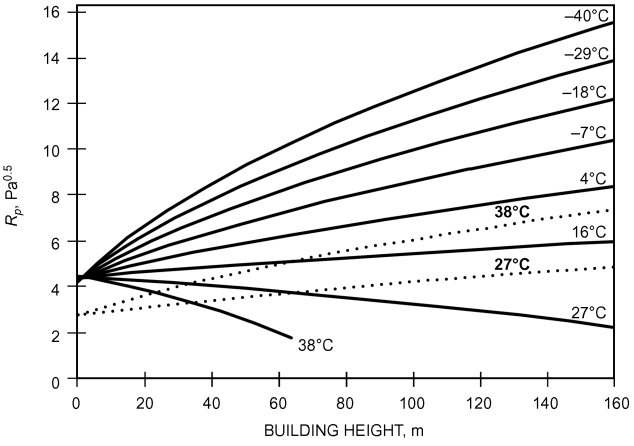

Fig. 16 Pressure Factor for Automatic Doors

Two simplified design methods are presented here. The first method uses practical assumptions to determine design values for R_p, the square root of the pressure difference across the automatic door, given in Figure 16. The second method requires explicit calculation of envelope pressures.

In Figure 16, airflows shown for outdoor air temperatures of 27 and 38°C, represented by dotted lines, are outward flows. They intercept the vertical axis at a lower point than the other lines because wind pressure coefficients on the building's downwind face, where the greatest outward flows occur, are lower than on the upward face. In many buildings, air pressure in the building is controlled by varying the flow rate through return or exhaust fan(s) or by controlling the relief air dampers. These systems are usually set to maintain a pressure slightly above ambient in the lobby, but in a large building, multiple sensors may be used to regulate air pressure on each floor independently, for example. Subtracting the interior pressure maintained from the wind pressure gives the net pressure for estimating airflow through an exterior door.

Method 1. For the first method, the infiltration rate through the automatic door is

$$Q = C_A A R_p \tag{52}$$

where

Q = airflow rate, L/s

Licensed for single user. © 2021 ASHRAE, Inc.

C_A = airflow coefficient from Figure 15, L/(s·m²·Pa^0.5)
A = area of the door opening, m²
R_p = pressure factor from Figure 16, Pa^0.5

Method 2. Airflow Q is

$$Q = C_A A \sqrt{\Delta p} \quad (53)$$

where

Q = airflow rate, L/s
C_A = airflow coefficient from Figure 15, L/(s·m²·Pa^0.5)
A = area of the door opening, m²
Δp = pressure difference across door, Pa

To find Δp, it is necessary to find the pressure differential created by both wind and stack effect. To give the largest possible pressure difference across the door, there are no interactions between the two natural pressures:

$$\Delta p = p_w - \Delta p_s \quad (54)$$

where

p_w = wind-induced surface pressure relative to static pressure, Pa
Δp_s = pressure difference caused by stack effect, Pa

Example Calculations

Find the maximum possible winter infiltration through an automatic door on the ground floor of a 20-story building. The area of the door is 0.91 × 2.1 m = 1.9 m². Each floor is 4 m high. Approximately 300 people per hour pass through the door. The design wind conditions are 6.7 m/s, indoor temperature is 21°C, and outdoor temperature is –7°C. The airflow coefficient from Figure 15, using the line for doors without vestibules, is approximately 306 L/(s·m²·Pa^0.5).

Method 1:

The pressure factor from Figure 16 is 9.6 Pa^0.5. Equation (52) gives the door's airflow as

$$Q = 306(1.9)9.6 = 5600 \text{ L/s}$$

Method 2:

The worst possible case for wind surface pressure coefficient C_p at any point and in any position on the ground floor of the building is inferred from the figures in Chapter 24 to be about 0.75. Using this in Equation (25), together with the specified wind speed, results in p_w = 20 Pa. Assume that H is one-half the door height (1.1 m). To have maximum pressure across the door, assume the neutral pressure plane is located halfway up the building such that

$$H_{NPL} = \frac{1}{2}(20 \text{ stories})\frac{4 \text{ m}}{\text{story}} = 40 \text{ m}$$

Substituting these values into Equation (24) gives Δp_s = –47 Pa. This is the maximum stack pressure difference given no internal resistance to airflow. To find the actual stack pressure difference, it is necessary to multiply this by a draft coefficient. For this example, the coefficient is assumed to be 0.9, which is the highest value that has been found for tall buildings. Therefore, $\Delta p_s = 0.9(—47 \text{ Pa}) = -42$ Pa. The total pressure is then $\Delta p = 20 - (-42) = 62$ Pa. Substituting into Equation (53),

$$Q = 306(1.9)\sqrt{62} = 4580 \text{ L/s}$$

If the building has a vestibule, the airflow coefficient is read from Figure 15 using the line for doors with vestibules, and it is approximately 208 L/(s·m²·Pa^0.5), reducing airflow to 3100 L/s into the building.

Standard-sized revolving doors are often used where there is high use, but typically not where people would often be carrying large bags or pushing carts. Dols et al. (2014) applied a coupled building energy and airflow simulation tool to simulate airflow through entry doors in a prototype medium office building created by Ng et al. (2012) and found that using a vestibule reduced infiltration through the building entrance by 23%. More information on predicting infiltration rates through standard and extra-large revolving doors is still needed.

Air Exchange Through Air Curtains

Air curtains are jets of air projected across envelope openings with the intention of reducing air exchange and the entrance of dust and insects, for example. They are commonly applied to loading dock doorways and high-use building entrances. Performance of air curtains strongly depends on factors such as jet characteristics, wind, and building pressurization. More discussion on air curtain performance is available in the research literature and in Chapter 20 of the 2020 *ASHRAE Handbook—HVAC Systems and Equipment*.

12. COMMERCIAL AND INSTITUTIONAL VENTILATION

ASHRAE *Standard* 62.1 contains requirements on ventilation and indoor air quality for commercial, institutional, and high-rise residential buildings. These requirements address system and equipment issues, design ventilation rates, commissioning and systems start-up, and operation and maintenance. The user's manual for *Standard* 62.1-2010 (ASHRAE 2010b) provides details to help design, install, and operate building systems to meet requirements. The design requirements include two alternative procedures:

- The prescriptive **ventilation rate procedure (VRP)** contains a table of outdoor air ventilation requirements for a variety of space types, with adjustments for air distribution in rooms and systems serving multiple spaces. These requirements consist of both a per-person rate and a per-floor-area rate. Minimum outdoor air ventilation rates are based, in part, on research by Berg-Munch et al. (1986), Cain et al. (1983), Iwashita et al. (1989), and Yaglou et al. (1936), as well as years of experience of designers and building operators.
- The performance **indoor air quality procedure (IAQP)** seeks acceptable indoor air quality by controlling indoor contaminant concentrations through source control, air cleaning, and ventilation. It allows for either or both improved indoor air quality and reduced energy consumption. Chapter 29 of the 2020 *ASHRAE Handbook—HVAC Systems and Equipment* has information on air cleaning.

The ventilation rate procedure is by far the more commonly used because of its prescriptive nature.

Combining source control and local exhaust, as opposed to dilution with ventilation air, is the method of choice in many industrial environments. Industrial ventilation is discussed in Chapters 31 and 32 of the 2019 *ASHRAE Handbook—HVAC Applications* and in *Industrial Ventilation: A Manual of Recommended Practice* (ACGIH 2016). Ventilation of medical facilities, where high indoor air quality is expected, is discussed in ASHRAE *Standard* 62.1, Chapter 8 of the 2019 *ASHRAE Handbook—HVAC Applications*, and other publications [e.g., FGI (2014)].

Commercial and institutional building ventilation systems are typically designed to provide slight pressurization to reduce infiltration. This pressurization is achieved by having the outdoor or make-up airflow rate higher than the exhaust or relief airflow rate. In these buildings, infiltration is therefore usually neglected in HVAC design except in areas such as lobbies and loading docks, where infiltration can be important because of doors. However, as discussed previously, this little to no infiltration may only be achieved in practice with very tight envelope construction (e.g., including a continuous air barrier). As discussed in the section on Driving Mechanisms for Ventilation and Infiltration, wind and stack effect can also cause significant infiltration and exfiltration. Ventilation airflow rates for commercial and institutional buildings are typically determined using procedures in ASHRAE *Standard* 62.1. In these procedures for designing mechanical ventilation systems, no credit is given for infiltration. However, weather-driven pressure differentials may be significant and need to be considered when designing the ventilation system.

Licensed for single user. © 2021 ASHRAE, Inc.

Ventilation Rate Procedure

Per ASHRAE *Standard* 62.1, the design ventilation rate is determined starting with a table of minimum ventilation requirements for different space types. These requirements are expressed as an outdoor airflow rate per occupant or per unit floor area, or often both, depending on space type. These ventilation rates are based on air pollutants generated by people, activities, and building materials and furnishings. The rates are then adjusted for various parameters (e.g., multiple zones, type of room air distribution).

The HVAC designer faces several challenges in designing an air distribution system to deliver outdoor air to building occupants. The first is to determine whether the outdoor air is acceptable for use, and to design a system for cleaning the air if it is not acceptable. A second is to design an air intake and distribution system that will *deliver* the required level of outdoor air to the occupied portions of the building, and not just *admit* it to an air handler. This outdoor air must be delivered not only at design conditions, but throughout the year. The task is complicated by weather-related variations in indoor/outdoor pressure difference. Other complications include pressure variations caused by building components such as intermittent exhaust fans or dirty filters, and probably most significantly by supply flow variations associated with variable-air-volume (VAV) systems (Janu et al. 1995; Mumma and Wong 1990). This delivery issue is related to the discussion in the section on Air Change Effectiveness.

Multiple Spaces

Many commercial and institutional buildings have multiple-zone, recirculating ventilation systems wherein one or more conventional air handlers condition a mixture of outdoor and recirculated air (**supply air**) to more than one ventilation zone. Each zone may have a different outdoor air fraction required by ASHRAE *Standard* 62.1, but each air handler can typically only provide one outdoor air fraction. Therefore, the zone that requires the greatest outdoor air fraction (the **critical zone**) defines the outdoor air intake rate of the air handler. Consequently, all other zones receive more outdoor air than their minimum requirement. These zones can be considered to have unused ventilation air, which could be returned to the air handler and recirculated; thus, the outdoor air fraction at the air handler could be reduced while still meeting the needs of the critical zone. A method to address multiple-zone recirculating systems, based on the system ventilation efficiency equation (SVEE), is provided in the ventilation rate procedure of *Standard* 62.1. ASHRAE-sponsored research experimentally tested the validity of this equation and confirmed that the SVEE is a valid predictor of ventilation distribution in a building (Yuill et al. 2012).

Secondary Path Systems. Some systems circulate unused ventilation air through paths other than through the central air handler. Common examples include transfer fans and fan-powered boxes. Warden (1995) suggested that *Standard* 62.1 should allow for the increased distribution efficiency that is possible with these systems, and presented a generalized SVEE that includes secondary air paths. A form of this equation is given in Equation (A-3) of ASHRAE *Standard* 62.1-2010.

Equation (A-3) depends on the ventilating ability of the secondary air E_r. The standard previously described E_r in terms of the proportion of average system return air directly recirculated from the critical zone. Yuill et al. (2008) argued that the formulation of Equation (A-3) implicitly defines E_r as a descriptor of the vitiation of the secondary air, and presented a formal definition of E_r, a version of which was adopted for *Standard* 62.1. Under this definition, if secondary air is drawn from an area that is less contaminated than the building average, values of E_r greater than 1 are possible. Yuill et al. (2012) measured E_r in several locations in an office building and found results ranging from 0.74 to 1.01. Results in the same building could have ranged from 0.14 to 1.13 if the fan-powered boxes had been located differently.

Survey of Ventilation Rates in Office Buildings

Relatively few measurements of as-built office building ventilation performance have been conducted, and those data generally have not used consistent measurement methods or involved representative collections of buildings. The U.S. Environmental Protection Agency (EPA) Building Assessment Survey and Evaluation (BASE) study involved indoor environmental measurements, including ventilation, in 100 randomly selected office buildings using a standardized protocol (EPA 2003). Persily et al. (2005) analyzed the BASE data and found that outdoor air ventilation rates measured using duct traverses at air handler intakes were higher than might be expected, with a mean of about 55 L/s per person. However, these elevated values are partially explained by low occupant density (mean of about four persons per 100 m^2) and high outdoor air fractions (mean of about 35%). Considering only values that correspond to minimum outdoor air intake, the mean ventilation rate was 11 L/s per workstation. About one-half the ventilation rates under minimum outdoor air intake were below 9.4 L/s per person. Another key outcome of this study is documentation of measured airflow rates that are quite different from their design values. This finding highlights the need for good system commissioning and maintenance to achieve design intent. Designing and configuring systems to encourage regular maintenance by providing easy access to key system components is also important.

13. OFFICE BUILDING EXAMPLE

Ventilation and infiltration principles from this chapter, *Standard* 62.1-2010, and elsewhere are applied to a conventional office building in Atlanta, Georgia. The infiltration, local exhaust, or ventilation airflow rates determined can be used later in the design process (1) as input for the heating and cooling load calculations; (2) for sizing fans, ducts, and dampers; and (3) for inclusion in the construction documents' air-handling units (AHUs) schedules and specifications.

This example relies on the 2010 edition of ASHRAE *Standard* 62.1; because this and other standards are updated frequently, users should check for the latest edition.

Location

The example building is about 13 km northeast of downtown Atlanta, and is close to a major highway and its access roads. Atlanta's climate is hot and humid in the summer, and has relatively mild winters. The average annual outdoor air temperature is about 15.9°C and the heating kelvin-days per year, base 18.3°C ($HKD_{18.3}$), are about 1814 (Rock 2005). From Chapter 14, the winter 99% design outdoor air (OA) temperature is –5°C, whereas the 1% cooling dry-bulb temperature is 32.8°C, with a mean coincident wet-bulb temperature of 23.3°C. The 99.6 and 0.4% design wind speeds are 5.4 m/s in the winter and 4 m/s in the summer, both from the northwest. Warm and humid winds also travel north from the Gulf of Mexico, and occasionally the wind is from the Atlantic Ocean from the southeast.

Building

The approximately 2835 m^2 building is a two-story, flat-roofed, slab-on-grade commercial office building with a substantial roof overhang in each direction. Materials and construction quality are average commercial grade. Double-paned windows, and similar spandrel glass, are fixed in their metal curtain wall frames; all windows are nonoperable. The remaining portions of the exterior walls are brick. There are relatively few exterior doors, as described later in this example. The building is surrounded by black asphalt driveways, a parking lot, and some vegetation. The nearby highway is across a parallel two-lane access road, to the northwest.

Licensed for single user. © 2021 ASHRAE, Inc.

Occupancy

The building is occupied during normal weekday business hours, and occasionally for special weekend events. Night and weekend thermostat setbacks are used. On the perimeter of the building are mostly single-person offices and conference rooms. The core of the building is mainly open plan with cubicle workspaces, as well as various support rooms, restrooms, two stair towers, and an elevator. There is a large mailroom on the first floor and a lunchroom on the second. Occupant density is high during workdays. The overhead fluorescent lighting is typical of such office buildings, and there are significant computing, printing, and copying equipment loads. Smoking is not allowed in the building.

The building is owner occupied. Owners generally have long-term interests in minimizing costs, and in maximizing indoor air quality and thermal comfort so that workers' productivity is high.

Infiltration

For this example, assume a conventional all-air overhead HVAC system, and that the building is well sealed. Consequently, a slightly positive overall building pressurization is assumed during occupied hours. Because water condensation in the exterior envelope of the building is possible, air pressurization should be as low as is practical, and continuous air and moisture retarders should be installed. As a more expensive alternative to slight pressurization, the automatic control system could actively manage the dampers' positions and fans' operation to maintain an average neutral pressurization, relative to the outdoors. In either case, a good assumption is that infiltration is minimized, the windows and spandrel glass are fixed and well sealed, and the exterior doors are normally kept closed. During high-wind conditions beyond design, windward perimeter spaces may have some infiltration loads, but under nonpeak outdoor temperatures, a well-zoned HVAC system should have enough capacity to handle these extra loads. If both the OA temperature and wind are extreme, then these upwind perimeter spaces may become slightly uncomfortable. These extreme conditions are expected to occur only a few hours in a typical year.

Spaces with exterior doors can experience significant infiltration loads when people enter and leave. First-floor vestibules on the north and south sides of the building help limit this infiltration through the two main entrances. The double doors from stair tower #2 have infrequent use, and a high level of thermal comfort in stair towers is not typically expected. Thus, brief infiltration surges in stair tower #2 are deemed acceptable. However, the doors from the parking lot to the mailroom are frequently used by staff for shipping, receiving, entrance, and egress, and infiltration loads on the vestibules and mailroom are of concern. Many designers choose to ignore these extra loads in pressurized buildings, because they are transient and not easily characterized; the systems' capacities are likely sufficient to minimize uncomfortable conditions in these spaces. In this example, however, the HVAC designer is concerned about summertime airborne moisture, especially in the mailroom where books and other publications are stored, because strong, humid, southerly winds easily overcome a slight indoor pressurization when the large doors to the parking lot are open.

This chapter and many of its supporting references describe detailed methods for estimating infiltration or air leakage. Typically, pressure differences, openings' coefficients, and hour-by-hour weather data are required to perform these transient calculations, usually using a computer program separate from that used for thermal load calculations. For HVAC design purposes for a building similar to the example, an air change rate of unconditioned outdoor air through infiltration, per space, expressed in air changes per hour or airflow rate (in L/s) is of more immediate use. Either value is then entered into the load calculation program. Unfortunately, accurate air changes per hour are difficult, if not impossible, to predict, so design estimates must be made. For example,

North Vestibule

- Gross floor area ≈ 3.4 m × 4 m = 13.6 m^2
- Room volume ≈ 13.6 m^2 × 2.7 m = 36.7 m^3
- ACH_{inf} ≈ 1.0, so
- Q_{inf} ≈ (36.7 m^3 × 1000 L/m^3 × 1.0)/3660 s/h ≈ 10.2 L/s outdoor air

Either 1.0 ach or 10.2 L/s of infiltration is then used as input for the load calculation program for this space. The 1.0 ach assumption was made by the designer during on-site observation that these particular manually operated exterior doors have low usage. If passage rates were known, Yuill's (1996) flow rate estimation method would have been used instead.

South Vestibule

- Gross floor area ≈ 2.4 m × 3 m = 7.2 m^2
- Room volume ≈ 7.2 m^2 × 2.7 m = 19.4 m^3
- ACH_{inf} ≈ 2.0, so
- Q_{inf} ≈ (19.4 m^3 × 1000 L/m^3 × 2.0)/3600 s/h ≈ 10.8 L/s outdoor air

In practice, this back entrance from the parking lot on the southeast side of the building is the primary means of entrance and egress, and as such, the estimated infiltration for it is increased to 2.0 ach, compared to the north vestibule's 1.0 ach.

In colder U.S. climates, it is common practice for low-cost commercial buildings to have only space heating, and not cooling, in stair towers and vestibules. However, for this building in the Southeast, the designer decided to provide cooling for these vestibules. Thus, the estimated infiltration rates are applied to both the heating and cooling load calculations for these spaces. The building's mailroom, which also has exterior doors, is to be heated and cooled, too.

Mailroom

- Gross floor area ≈ (15.5 m × 6.7 m) + (10 m × 3 m) = 134 m^2
- Room volume ≈ 134 m^2 × 2.7 m = 362 m^3
- ACH_{inf} ≈ 0.5, so
- Q_{inf} ≈ (362 m^3 × 1000 L/m^3 × 0.5)/3600 s/h ≈ 50.3 L/s outdoor air

Even though the mailroom has only a single layer of doors to the outdoors, and not a vestibule, the designer estimated the infiltration at a lower rate (0.5 ach) than those for the vestibules. This is because of the mailroom's large interior volume relative to its exterior doorway's area.

Note that *no* estimate of air changes will be accurate at all times; this portion of HVAC design is still largely an art because of the many unknowns and variability of weather and building use. For improved energy conservation, all exterior doors must be extremely well weatherstripped and have automatic closers. A sign indicating that the doors should be kept closed when not in use should be placed on the mailroom's exterior doors. High-quality gaskets and sealants for the windows and spandrel glass are also required to minimize infiltration.

Local Exhausts

(This section assumes that ANSI/ASHRAE *Standard* 62.1-2010 has been adopted into the local building code without modification.) At least 10 rooms require direct, powered air exhaust: two restrooms per floor, a darkroom, three designated photocopy spaces, and two janitors' closets. The restrooms have three flushable fixtures each, so from Table 6-4 of *Standard* 62.1-2010, with intermittent use, each restroom requires

$$Q_{ea} = 3 \text{ units} \times 25 \text{ L/s per unit} = 75 \text{ L/s}$$

Also from Table 6-4, the darkroom on the second floor needs

$$\text{Gross floor area} \approx 3 \text{ m} \times 4.6 \text{ m} = 13.8 \text{ m}^2$$

Licensed for single user. © 2021 ASHRAE, Inc.

$$Q_{ea} = 13.8 \text{ m}^2 \times 5.0 \text{ L/(s·m}^2) = 69 \text{ L/s}$$

Similarly, the designated photocopy areas need 2.5 L/(s·m^2), so

First floor, plan east: ≈7.4 m^2 × 2.5 L/(s·m^2) = 18.5 L/s exhaust air

First floor, plan southwest:
≈14.9 m^2 × 2.5 L/(s·m^2) = 37.3 L/s exhaust air

Second floor, plan east: ≈10.4 m^2 × 2.5 L/(s·m^2) = 26 L/s exhaust air

The two small janitors' closets, one on each floor, also require exhaust:

$$5.6 \text{ m}^2 \times 5.0 \text{ L/(s·m}^2) = 28 \text{ L/s exhaust air}$$

These local exhaust airflow rates are then entered into the load calculation program. They are room loads, attached to each particular space, and are *not* combined and entered as systems-level loads. The load calculation program evaluates the room loads, appropriately combines them, and then finds the systems-level loads for various peak hours.

Some local code authorities amend the requirements of *Standard* 62.1, or have not yet adopted the most current version, so significant deviations from these examples are possible. For example, in much of the United States, janitorial closets and photocopy rooms have not been required to have local exhausts. *Standard* 62.1-2010 recognized that these spaces can be significant sources of airborne pollutants, and some direct exhaust from each of them can be very beneficial for improving indoor air quality.

Ventilation

(This section also assumes that ANSI/ASHRAE *Standard* 62.1-2010 has been adopted into local code without changes.) Ventilation air is needed to maintain acceptable indoor air quality. The example building is well sealed, natural ventilation is not used, and no credit for any infiltration is taken toward ventilation air requirements, as is typical for conventional commercial buildings. Thus, minimum ventilation air required by *Standard* 62.1 is provided mechanically through the building's AHUs. Because smoking is not allowed in the building, no extra ventilation for environmental tobacco smoke (ETS) is needed. However, considering outdoor air pollution from the major highway nearby as well as metropolitan Atlanta's smog, some outdoor air pretreatment may be considered later in the design process.

Standard 62.1 has two methods for determining needed ventilation airflow rates: the performance IAQ procedure (IAQP), and the prescriptive ventilation rate procedure (VRP). Most HVAC designers of conventional buildings with normal occupancies and outdoor air conditions use the VRP, which is appropriate for this example building.

Required ventilation air, which is solely conditioned outdoor air, is admitted to this building through two air-handling units; each AHU serves one floor. Flow rates of outdoor air are input values for, and carried through to the results of, the load calculation simulation. Energy needed to condition the outdoor air ultimately is a systems-level load, because all of this ventilation air is conditioned by the AHUs before its introduction to the building.

Commercial load calculation programs often provide suggested values of ventilation airflow rates and occupancy schedules, but may not have been updated to reflect the latest VRP requirements and procedures of *Standard* 62.1. As such, it is difficult to present an example here; instead, a sample check using some assumed values for the first-floor executive director's office is given. It is assumed that this room is a separate thermal zone because of its use and its location on the southwest corner of the building and thus two afternoon solar exposures.

Executive Director's Office

- Gross floor area ≈ 3.7 m × 6.4 m = 23.7 m^2
- Room volume ≈ 23.7 m^2 × 2.7 m = 64 m^3
- Assumed supply air Q_{sa} = 194 L/s

The supply airflow rate was estimated using 7.93 m^2/kW, a sensible heat factor of 0.9, a cooling supply (12.8°C) to room (23.9°C) air temperature difference of 11.1 K, 1000 W per kW of cooling, and the sensible heat equation 1.23 × L/s × ΔT. From Table 6-1 of *Standard* 62.1-2010, the office's population P can be estimated as

$$P = 23.7 \text{ m}^2 \times 5 \text{ occupants}/100 \text{ m}^2 = 1.19$$

In this case, however, there is only one regular occupant of the space. The needed ventilation airflow rate to the breathing zone V_{bz} is then found from the table as follows:

$$V_{bz} = R_p P_z + R_a A_z$$

$$V_{bz} = [2.5 \text{ L/(s·person)} \times 1 \text{ person}] + [0.3 \text{ L/(s·m}^2) \times 23.7 \text{ m}^2] = 9.61 \text{ L/s}$$

where

R_p = outdoor airflow rate required per person, from *Standard* 62.1's Table 6-1, L/s
P_z = zone population (largest number of people expected to occupy the zone during typical use)
R_a = outdoor airflow rate required per unit area, from *Standard* 62.1's Table 6-1, L/s
A_z = occupiable floor area of zone, m^2

Note that *Standard* 62.1's VRP includes a building component $R_a A_z$, as well as the traditional per-person people component.

Because this is a conventional office building, with ceiling plenums and no raised floors, overhead air supply and return is assumed. The cooling mode, not heating, is dominant in this and most other U.S. office buildings that have high internal heat gains and well-sealed and insulated envelopes. From the standard's Table 6-2, with ceiling supply of cool air, the zone air distribution effectiveness E_z is estimated as 1.0. From Equation (6-2) of the standard, the design zone outdoor airflow rate V_{oz} is then

$$V_{oz} = V_{bz}/E_z = (9.61 \text{ L/s})/1.0 = 9.61 \text{ L/s}$$

But this is still not the amount of outdoor air that must be conditioned by the air handler: the rate must be adjusted for inefficiencies and recirculation in the air distribution system.

Because single-duct VAV with terminal reheat air distribution systems were initially planned by the designer, *Standard* 62.1's multiple-zone recirculating systems adjustment is needed. For this thermal zone, the primary outdoor air fraction Z_p for its VAV terminal unit and downstream is

$$Z_p = V_{oz}/V_{pz} = (9.61 \text{ L/s})/(194 \text{ L/s}) = 0.05, \text{ or } 5\%$$

However, for VAV systems, the minimum expected primary airflow rate should be used. In this case, 194 L/s is the peak design airflow rate. Designers often assume about 30% of this peak flow as the minimum in VAV systems, so for this space, 194 × 0.3 = 58.2 L/s. The adjusted primary outdoor air fraction is then

$$Z_p = V_{oz}/V_{pz} = (9.61 \text{ L/s})/(58.2 \text{ L/s}) = 0.17, \text{ or } 17\%$$

The preceding calculations need to be performed for every thermal zone on each air handler. Then, for each system, the highest primary outdoor air fraction is used to estimate the air distribution systems' ventilation effectiveness; the 62.1 user's manual (ASHRAE 2010b) includes a spreadsheet for doing these calculations. Increasingly, load calculation programs include the necessary routines and data.

Licensed for single user. © 2021 ASHRAE, Inc.

For the purposes of this example, 0.17 is assumed to be the maximum Z_p, so, from Table 6.3 of *Standard* 62.1, the system ventilation efficiency E_v is 0.9. If, instead, the standard's Appendix A method for determining E_v were used, a value closer to 1.0 for perfect mixing would likely result for this example's conventional overhead all-air cooling system. Table 6-3's value of 0.9 is likely somewhat conservative, but is obtained quickly for design purposes.

Next, the uncorrected outdoor air intake flow rate V_{ou} is needed; *Standard* 62.1's Equation (6-6) includes diversity factor D to adjust the people component of the flow rate. All zones' flow rates are needed to perform this calculation. For this example, the uncorrected outdoor air intake flow rate for the first floor's AHU was estimated from floor area, an occupancy of 5 people per 100 m^2, and 9.4 L/s per person, and is assumed to be 720 L/s. The adjusted outdoor air intake flow rate V_{ot} for this AHU is then

$$V_{ot} = V_{ou}/E_v = (720 \text{ L/s})/0.9 = 800 \text{ L/s outdoor air}$$

After load calculations are complete, these assumed airflow rates can be replaced with actual values for each zone, and the outdoor airflow rate can be updated. Repeating the load calculations may be necessary. The final value of the adjusted outdoor air intake flow rate is then reported on the AHU's equipment schedule so that testing, adjusting, and balancing (TAB) personnel and others can use this information to ensure that the system admits the desired flow rate of ventilation air. The information is also used to select air cleaners, dampers, coils, ducts, and fans.

For more examples on determining ventilation air rates for commercial buildings, see the user's manual for *Standard* 62.1 (ASHRAE 2010b). For low-rise residential buildings, consult ASHRAE *Standard* 62.2 and its user's manual (ASHRAE 2010a).

14. SYMBOLS

A = area, m^2 or cm^2
c = flow coefficient, m^3/(s·Pa^n)
c_p = specific heat, J/(kg·K) or kJ/(kg·K)
C = concentration, ppm
$\bar{C}$ = time averaged concentration
C_A = airflow coefficient for automatic doors, L/(s·m^2·Pa$^{0.5}$)
C_D = discharge coefficient
C_p = pressure coefficient
C_s = stack flow coefficient, (L/s)^2/(cm^4·K) or (Pa/K)^n
C_v = effectiveness of openings
C_w = wind flow coefficient, (L/s)^2[cm^4·(m/s)^2] or [Pa/(m/s)^2]^n
E = system efficiency
ELA = effective leakage area
F = tracer gas injection rate, m^3/s
$\bar{F}$ = time-averaged contaminant source strength, m^3/s
f = fractional on-time
g = gravitational acceleration, m/s^2
G = wind speed multiplier, Table 7
h = specific enthalpy, kJ/kg
H = height, m
i = hour of year
I = air change rate, 1/time
I_i = instantaneous air change rate, 1/time
I_m = effective air change rate, 1/time
IDD = infiltration degree-days, K·day/yr
L = leakage area, m^2 or cm^2
n = pressure exponent
N = number of discrete time periods in period of interest
NL = normalized leakage
p = pressure, Pa
P = parameter, or number of people
q = heat rate, W
Q = volumetric flow rate, m^3/s
$\bar{Q}$ = effective volumetric flow rate, m^3/s
R = outdoor airflow rate, L/s
s = shelter factor
S = source strength, m^3/s
t = time
T = temperature, °C or K
U = wind speed, m/s
V = volume, m^3, or ventilation airflow rate, L/s
W = humidity ratio, kg/kg
ε_I = air change effectiveness
θ_{age} = age of air, s, min, or h
ρ = air density, kg/m^3
τ = time constant, s, min, or h
ϕ = wind angle, degrees

Subscripts

a = area
b = base
ba = bypass air
bz = breathing zone
c = calculated
ca = recirculated air
da = dry air
$depress$ = depressurization
e = effective
ea = exhaust air
f = floor
i = indoor or time counter for summation (instantaneous)
inf = infiltration
H = building height, eaves or roof
ka = makeup air
l = latent
la = relief air
L = leakage or local
ma = mixed air
met = meteorological station location
n = normalized
N = nominal
NPL = neutral pressure level
o = outdoor, initial condition, or reference
oa = outdoor air
ot = adjusted outdoor air
ou = uncorrected outdoor air
oz = zone outdoor
p = pressure, or primary
$press$ = pressurization
r = reference
s = sensible or stack
sa = supply air
S = space or source
w = wind or water
v = ventilation
z = zone

RESIDENTIAL COOLING AND HEATING LOAD CALCULATIONS

Residential Features 17.1
Calculation Approach 17.1
Other Methods 17.2
Residential Heat Balance (RHB) Method 17.2
Residential Load Factor (RLF) Method 17.2
Common Data and Procedures 17.2
Cooling Load 17.8
Heating Load 17.11
Load Calculation Example 17.12
Symbols 17.14

THIS chapter covers cooling and heating load calculation procedures for residential buildings, including detailed heat-balance methods that serve as the basis for cooling load calculation. Simple cooling load procedures, suitable for hand calculations, are provided for typical cases. Straightforward heating load calculation procedures are also included.

Procedures in this chapter are based on the same fundamentals as the nonresidential methods in Chapter 18. However, many characteristics distinguish residential loads, and Chapter 18's procedures should be applied with care to residential applications.

Additional information about residential heating and cooling is found in Chapter 1 of the 2019 *ASHRAE Handbook—HVAC Applications* and Chapter 10 of the 2020 *ASHRAE Handbook—HVAC Systems and Equipment*.

1. RESIDENTIAL FEATURES

With respect to heating and cooling load calculation and equipment sizing, the following unique features distinguish residences from other types of buildings:

- **Smaller Internal Heat Gains.** Residential system loads are primarily imposed by heat gain or loss through structural components and by air leakage or ventilation. Internal heat gains, particularly those from occupants and lights, are small compared to those in commercial or industrial structures.
- **Varied Use of Spaces.** Use of spaces in residences is more flexible than in commercial buildings. Localized or temporary temperature excursions are often tolerable.
- **Fewer Zones.** Residences are generally conditioned as a single zone or, at most, a few zones. Typically, a thermostat located in one room controls unit output for multiple rooms, and capacity cannot be redistributed from one area to another as loads change over the day. This results in some hour-to-hour temperature variation or swing that has a significant moderating effect on peak loads, because of heat storage in building components.
- **Greater Distribution Losses.** Residential ducts are frequently installed in attics or other unconditioned buffer spaces. Duct leakage and heat gain or loss can require significant increases in unit capacity. Residential distribution gains and losses cannot be neglected or estimated with simple rules of thumb.
- **Partial Loads.** Most residential cooling systems use units of relatively small capacity (about 5 to 18 kW cooling, 18 to 32 kW heating). Because loads are largely determined by outdoor conditions, and few days each season are design days, the unit operates at partial load during most of the season; thus, an oversized unit is detrimental to good system performance, especially for cooling in areas of high wet-bulb temperature.
- **Dehumidification Issues.** Dehumidification occurs during cooling unit operation only, and space condition control is usually limited to use of room thermostats (sensible heat-actuated devices). Excessive sensible capacity results in short-cycling and severely degraded dehumidification performance.

In addition to these general features, residential buildings can be categorized according to their exposure:

- **Single-Family Detached.** A house in this category usually has exposed walls in four directions, often more than one story, and a roof. The cooling system is a single-zone, unitary system with a single thermostat. Two-story houses may have a separate cooling system for each floor. Rooms are reasonably open and generally have a centralized air return. In this configuration, both air and load from rooms are mixed, and a load-leveling effect, which requires a distribution of air to each room that is different from a pure commercial system, results. Because the amount of air supplied to each room is based on the load for that room, proper load calculation procedures must be used.
- **Multifamily.** Unlike single-family detached units, multifamily units generally do not have exposed surfaces facing in all directions. Rather, each unit typically has a maximum of three exposed walls and possibly a roof. Each living unit has a single unitary cooling system or a single fan-coil unit and the rooms are relatively open to one another. This configuration does not have the same load-leveling effect as a single-family detached house.
- **Other.** Many buildings do not fall into either of the preceding categories. Critical to the designation of a single-family detached building is well-distributed exposure so there is not a short-duration peak; however, if fenestration exposure is predominantly east or west, the cooling load profile resembles that of a multifamily unit. On the other hand, multifamily units with both east and west exposures or neither east nor west exposure exhibit load profiles similar to single-family detached.

2. CALCULATION APPROACH

Variations in the characteristics of residences can lead to surprisingly complex load calculations. Time-varying heat flows combine to produce a time-varying load. The relative magnitude and pattern of the heat flows depends on the building characteristics and exposure, resulting in a building-specific load profile. In general, an hour-by-hour analysis is required to determine that profile and find its peak.

In theory, cooling and heating processes are identical; a common analysis procedure should apply to either. Acceptable simplifications are possible for heating; however, for cooling, different approaches are used.

Heating calculations use simple worst-case assumptions: no solar or internal gains, and no heat storage (with all heat losses evaluated instantaneously). With these simplifications, the heating problem is reduced to a basic $UA\Delta t$ calculation. The heating

The preparation of this chapter is assigned to TC 4.1, Load Calculation Data and Procedures.

Licensed for single user. © 2021 ASHRAE, Inc.

procedures in this chapter use this long-accepted approach, and thus differ only in details from prior methods put forth by ASHRAE and others.

The cooling procedures in this chapter were extensively revised in 2005, based on the results of ASHRAE research project RP-1199, also supported by the Air-Conditioning Contractors of America (ACCA) (Barnaby et al. 2004, 2005). Although the complexity of residential cooling load calculations has been understood for decades, prior methods used a cooling load temperature difference/cooling load factor (CLTD/CLF) form requiring only hand-tractable arithmetic. Without such simplification, the procedures would not have been used; an approximate calculation was preferable to none at all. The simplified approaches were developed using detailed computer models and/or empirical data, but only the simplifications were published. Now that computing power is routinely available, it is appropriate to promulgate 24 h, equation-based procedures.

3. OTHER METHODS

Several residential load calculation methods have been published in North America over the last 30 years. All use the $UA\Delta t$ heating formulation and some variation of the CLTD/CLF approach for cooling.

- **ACCA.** *Manual J*, 8th edition (ACCA 2016) is widely used in the United States. Cooling loads are calculated using semiempirical heat gain factors derived from experimental data taken at the University of Illinois in the 1950s. These factors, associated overview, and references are found in the 1985 and earlier editions of the *ASHRAE Handbook—Fundamentals*. The 8th edition retains the underlying factors but provides increased flexibility in their application, in addition to other extensions.
- **ASHRAE.** The 1989 to 2001 editions of the *ASHRAE Handbook—Fundamentals* contain an updated method based on ASHRAE research project RP-342 (McQuiston 1984). In this work, cooling factors were re-derived using a transfer-function building model that included temperature-swing effects.
- **F280.** This Canadian adaptation of the CLTD/CLF procedure (CAN/CSA *Standard* F280) also uses cooling methods based on ASHRAE RP-342. Heating procedures include detailed ground heat loss estimates.

A key common element of all cooling methods is attention to temperature swing, via empirical data or suitable models. Throughout the literature, it is repeatedly emphasized that direct application of nonresidential methods (based on a fixed set point) results in unrealistically high cooling loads for residential applications.

4. RESIDENTIAL HEAT BALANCE (RHB) METHOD

A 24 h procedure is required to accurately determine the cooling load profile of a residence. The heat balance (HB) method allows detailed simulation of space temperatures and heat flows. ASHRAE research project RP-1199 adapted HB to residential applications, resulting in the residential heat balance (RHB) method. Although RHB provides the technical basis for this chapter, it is a computer-only technique and is not documented here. HB is described in Chapter 18 and Pedersen et al. 1998; Barnaby et al. (2004, 2005) document RHB enhancements.

RP-1199 produced an implementation of the RHB method, called ResHB (Barnaby et al. 2004). This application is derived from the ASHRAE *Toolkit for Building Load Calculations* (Pedersen et al. 2001) and has the following features:

- **Multizone.** Whereas the original *Toolkit* code supported a single zone, ResHB can analyze projects that include multiple systems, zones, and rooms.
- **Temperature swing.** ResHB calculates cooling load with temperature swing. That is, the code searches for sensible capacity sufficient to hold the space temperature within a specified excursion above the set point.
- **Master/slave control.** ResHB allows control of cooling output in "slave" rooms based on the cooling requirements of a "master" room, where the thermostat is located. Rooms with incompatible load profiles will exhibit poor temperature control.
- **Residential defaults.** ResHB includes default values suitable for residential problems.

In its current form, ResHB is a research-oriented reference implementation of RHB. ResHB FORTRAN source code is available under license from ASHRAE.

5. RESIDENTIAL LOAD FACTOR (RLF) METHOD

The procedure presented in this chapter is the residential load factor (RLF) method. RLF is a simplified procedure derived from detailed ResHB analysis of prototypical buildings across a range of climates. The method is tractable by hand but is best applied using a spreadsheet. Two main applications are anticipated:

- **Education and training.** The transparency and simplicity of RLF make it suitable for use in introductory courses on building load calculations.
- **Quick load estimates.** In situations where detailed analysis is impractical, the RLF method is a possible alternative. For example, the method might be implemented as a spreadsheet on a handheld device and used for on-site sizing of replacement cooling equipment.

Note that, although room-by-room calculations are possible with the RLF method, computerized methods based on RHB are more suitable for performing full room-level calculations required for equipment selection and distribution system design.

RLF was derived from several thousand ResHB cooling load results (Barnaby and Spitler 2005; Barnaby et al. 2004). A range of climates and building types were analyzed. Statistical regression techniques were used to find values for the load factors tabulated in later sections. Factor values were validated by comparing ResHB versus RLF results for buildings not involved in the regression analysis. Within its range of applicability, RLF cooling loads are generally within 10% of those calculated with ResHB. The RLF derivation was repeated for 2009 using the updated temperature profile and clear-sky model (see Chapter 14), resulting in minor revisions to load factors and other coefficients. Additional revisions to Chapter 14 occurred in 2013 and 2017; those changes would alter RLF values very little, so the 2009 factors are retained.

The RLF method should not be applied to situations outside the range of underlying cases, as shown in Table 1.

Note that the RLF calculation sequence involves two distinct steps. First, the cooling and heating load factors (CFs and HFs) are derived for all project component types. These factors are then applied to the individual components by a single multiplication. (The two-step approach is demonstrated in the Load Calculation Example section.) For a specific location and representative constructions, CFs and HFs can be precalculated and used repeatedly. In essence, the structure of RLF allows assembling location-specific versions of the rigid tables found in prior editions, and also documents the equations used to generate tabulated values. Using these equations, a complete implementation of the RLF method, including CF and HF calculation, is well within the capabilities of current PC spreadsheet applications.

6. COMMON DATA AND PROCEDURES

The following guidelines, data requirements, and procedures apply to all load calculation approaches, whether heating or cooling, hand-tractable or computerized.

Licensed for single user. © 2021 ASHRAE, Inc.

Table 1 RLF Limitations

Item	Valid Range	Notes
Latitude	20 to 60°N	Also approximately valid for 20 to 60°S with N and S orientations reversed for southern hemisphere.
Date	July 21	Application must be summer peaking. Buildings in mild climates with significant SE/S/SW glazing may experience maximum cooling load in fall or even winter. Use RHB if local experience indicates this is a possibility.
Elevation	Less than 2000 m	RLF factors assume 50 m elevation. With elevation-corrected C_s, method is acceptably accurate except at very high elevations.
Climate	Warm/hot	Design-day average outdoor temperature assumed to be above indoor design temperature.
Construction	Lightweight residential construction (wood or metal framing, wood or stucco siding)	May be applied to masonry veneer over frame construction; results are conservative. Use RHB for structural masonry or unconventional construction.
Fenestration area	0 to 15% of floor area on any façade, 0 to 30% of floor area total	Spaces with high fenestration fraction should be analyzed with RHB.
Fenestration tilt	Vertical or horizontal	Skylights with tilt less than 30° can be treated as horizontal. Buildings with significant sloped glazing areas should be analyzed with RHB.
Occupancy	Residential	Applications with high internal gains and/or high occupant density should be analyzed with RHB or nonresidential procedures.
Temperature swing	1.7 K	
Distribution losses	Typical	Applications with extensive duct runs in unconditioned spaces should be analyzed with RHB.

General Guidelines

Design for Typical Building Use. In general, residential systems should be designed to meet representative maximum-load conditions, not extreme conditions. Normal occupancy should be assumed, not the maximum that might occur during an occasional social function. Intermittently operated ventilation fans should be assumed to be off. These considerations are especially important for cooling-system sizing.

Building Codes and Standards. This chapter presentation is necessarily general. Codes and regulations take precedence; consult local authorities to determine applicable requirements.

Designer Judgment. Designer experience with local conditions, building practices, and prior projects should be considered when applying the procedures in this chapter. For equipment-replacement projects, occupant knowledge concerning performance of the existing system can often provide useful guidance for achieving a successful design.

Verification. Postconstruction commissioning and verification are important steps in achieving design performance. Designers should encourage pressurization testing and other procedures that allow identification and repair of construction shortcomings.

Uncertainty and Safety Allowances. Residential load calculations are inherently approximate. Many building characteristics are estimated during design and ultimately determined by construction quality and occupant behavior. These uncertainties apply to all calculation methods, including first-principles procedures such as RHB. It is therefore tempting to include safety allowances for each aspect of a calculation. However, this practice has a compounding effect and often produces oversized results. Typical conditions should be assumed; safety allowances, if applied at all, should be added to the final calculated loads rather than to intermediate components. In addition, temperature swing provides a built-in safety factor for sensible cooling: a 20% capacity shortfall typically results in a temperature excursion of at most about one or two degrees.

Basic Relationships

Common air-conditioning processes involve transferring heat via air transport or leakage. The sensible, latent, and total heat conveyed by air on a volumetric basis is

$$q_s = C_s Q \Delta t \quad (1)$$

$$q_l = C_l Q \Delta W \quad (2)$$

$$q_t = C_t Q \Delta h \quad (3)$$

$$q_t = q_s + q_l \quad (4)$$

where

q_s, q_l, q_t = sensible, latent, total heat transfer rates, W
C_s = air sensible heat factor, W/(L·s·K) (1.23 at sea level)
C_l = air latent heat factor, W/(L·s) (3010 at sea level)
C_t = air total heat factor, W/(L·s) per kJ/kg enthalpy h (1.2 at sea level)
Q = air volumetric flow rate, L/s
Δt = air temperature difference across process, K
ΔW = air humidity ratio difference across process, kg_w/kg_{da}
Δh = air enthalpy difference across process, kJ/kg

The heat factors C_s, C_l, and C_t are elevation dependent. The sea-level values in the preceding definitions are appropriate for elevations up to about 300 m. Procedures are provided in Chapter 18 for calculating adjusted values for higher elevations.

Design Conditions

The initial step in the load calculation is selecting indoor and outdoor design conditions.

Indoor Conditions. Indoor conditions assumed for design purposes depend on building use, type of occupancy, and/or code requirements. Chapter 9 and ASHRAE *Standard* 55 define the relationship between indoor conditions and comfort.

Typical practice for cooling is to design for indoor conditions of 24°C db and a maximum of 50 to 65% rh. For heating, 20°C db and 30% rh are common design values. These conditions are the default values used throughout this chapter.

Outdoor Conditions. Outdoor design conditions for load calculations should be selected from location-specific climate data in Chapter 14, or according to local code requirements as applicable.

Cooling. The 1% design dry-bulb temperature and mean coincident wet bulb temperature from Chapter 14 climate data are generally appropriate. As previously emphasized, oversized cooling equipment results in poor system performance. Extremely hot events are necessarily of short duration (conditions always moderate each night); therefore, sacrificing comfort under typical conditions to meet occasional extremes is not recommended.

Load calculations also require the hottest-month dry-bulb temperature daily range, and wind speed. These values can also be found in Chapter 14, although wind speed is commonly assumed to be 3.4 m/s.

Typical buildings in middle latitudes generally experience maximum cooling requirements in midsummer (July in the northern hemisphere and January in the southern hemisphere). For this reason, the

Licensed for single user. © 2021 ASHRAE, Inc.

RLF method is based on midsummer solar gains. However, this pattern does not always hold. Buildings at low latitudes or with significant south-facing glazing (north-facing in the southern hemisphere) should be analyzed at several times of the year using the RHB method. Local experience can provide guidance as to when maximum cooling is probable. For example, it is common for south-facing buildings in mild northern-hemisphere climates to have peak cooling loads in the fall because of low sun angles. Chapter 14 contains monthly temperature data to support calculations for any time of year.

Heating. General practice is to use the 99% design dry-bulb temperature from Chapter 14. Heating load calculations ignore solar and internal gains, providing a built-in safety factor. However, the designer should consider two additional factors:

- Many locations experience protracted (several-day) cold periods during which the outdoor temperature remains below the 99% value.
- Wind is a major determinant of infiltration. Residences with significant leakage (e.g., older houses) may have peak heating demand under conditions other than extreme cold, depending on site wind patterns.

Depending on the application and system type, the designer should consider using the 99.6% value or the mean minimum extreme as the heating design temperature. Alternatively, the heating load can be calculated at the 99% condition and a safety factor applied when equipment is selected. This additional capacity can also serve to meet pickup loads under nonextreme conditions.

Adjacent Buffer Spaces. Residential buildings often include unconditioned buffer spaces such as garages, attics, crawlspaces, basements, or enclosed porches. Accurate load calculations require the adjacent air temperature.

In many cases, a simple, conservative estimate is adequate, especially for heating calculations. For example, it is generally reasonable to assume that, under heating design conditions, adjacent uninsulated garages, porches, and attics are at outdoor temperature. Another reasonable assumption is that the temperature in an adjacent, unheated, *insulated* room is the mean of the indoor and outdoor temperatures.

In cases where a temperature estimate is required, a steady-state heat balance analysis yields the following:

$$t_b = \frac{C_s Q t_o + \sum A_x U_x t_x + q}{C_s Q + \sum A_x U_x} \quad (5)$$

where

t_b = buffer space temperature, °C
Q = buffer space infiltration/ventilation flow rate, L/s
t_o = outdoor air temperature, °C
A_x = area of xth buffer space surface, m^2
U_x = U-factor of xth buffer space surface, $W/(m^2 \cdot K)$
t_x = air temperature at outside of xth buffer space surface, °C (typically, outdoor air temperature for exterior surfaces, conditioned space temperature for surfaces between buffer space and house, or ground temperature for below-grade surfaces)
q = additional buffer space heat gains, W (e.g., solar gains or distribution system losses)

Building Data

Component Areas. To perform load calculations efficiently and reliably, standard methods must be used for determining building surface areas. For fenestration, the definition of component area must be consistent with associated ratings.

Gross area. It is both efficient and conservative to derive gross surface areas from outer building dimensions, ignoring wall and floor thicknesses. Thus, floor areas should be measured to the outside of adjacent exterior walls or to the centerline of adjacent partitions. When apportioning to rooms, façade area should be divided at partition centerlines. Wall height should be taken as floor-to-floor.

Using outer dimensions avoids separate accounting of floor edge and wall corner conditions. Further, it is standard practice in residential construction to define floor area in terms of outer dimensions, so outer-dimension takeoffs yield areas that can be readily checked against building plans (e.g., the sum of room areas should equal the plan floor area). Although outer-dimension procedures are recommended as expedient for load calculations, they are not consistent with rigorous definitions used in building-related standards (e.g., ASTM *Standard* E631). However, the inconsistencies are not significant in the load calculation context.

Fenestration area. Fenestration includes exterior windows, skylights, and doors. Fenestration U-factor and SHGC ratings (see Table 2) are based on the entire product area, including frames. Thus, for load calculations, fenestration area is the area of the rough opening in the wall or roof, less installation clearances (projected product area A_{pf}). Installation clearances can be neglected; it is acceptable to use the rough opening as an approximation of A_{pf}.

Net area. Net surface area is the gross surface area less fenestration area (rough opening or A_{pf}) contained within the surface.

Volume. Building volume is expediently calculated by multiplying floor area by floor-to-floor height. This produces a conservative estimate of enclosed air volume, because wall and floor volumes are included in the total. More precise calculations are possible but are generally not justified in this context.

Construction Characteristics.

U-factors. Except for fenestration, construction U-factors should be calculated using procedures in Chapter 27, or taken from manufacturer's data, if available. U-factors should be evaluated under heating (winter) conditions.

Fenestration. Fenestration is characterized by U-factor and solar heat gain coefficient (SHGC), which apply to the entire assembly (including frames). If available, rated values should be used, determined according to procedures set forth by National Fenestration Rating Council (NFRC), Canadian Standards Association (CSA), or other specifying body (see Chapter 15). Ratings can be obtained from product literature, product label, or online listings (NFRC 2017). For unrated products (e.g., in existing construction), the U-factor and SHGC can be estimated using Table 2 or tables in Chapter 15. Note that fenestration U-factors are evaluated under heating (winter) design conditions but are used in this chapter for both heating and cooling calculations.

Relatively few types of glazing are encountered in residential applications. Single-glazed clear, double-glazed clear, and double-glazed low-emissivity ("low-e") glass predominate. Single-glazed is now rare in new construction but common in older homes. Triple-glazing, reflective glass, and heat-absorbing glass are encountered occasionally. Acrylic or glass skylights are common. Multipane low-e insulated glazing is available in high- and low-solar-gain variants, as discussed in Chapter 15. Low-solar is now the more common for new construction in all parts of the United States.

Properties of windows equipped with storm windows should be estimated from data for a similar configuration with an additional pane. For example, data for clear, double-glazed should be used for a clear single-glazed window with a storm window.

Fenestration interior and exterior shading must be included in cooling load calculations, as discussed in the Cooling Load section.

Table 2 shows representative window U-factor and SHGC values for common glazing and frame combinations. Consult Chapter 15 for skylight characteristics.

Load Components

Below-Grade Surfaces. For cooling calculations, heat flow into the ground is usually ignored because it is difficult to quantify.

[a]Data are from Chapter 15, Tables 4 and 14 for selected combinations. [b]ID = Chapter 15 glazing type identifier. [c]*U* = U-factor, W/(m²·K). [d]SHGC = solar heat gain coefficient.

Surfaces adjacent to the ground are modeled as if well insulated on the outside, so there is no overall heat transfer, but diurnal heat storage effects are included. Heating calculations must include loss via slabs and basement walls and floors, as discussed in the Heating Load section.

Infiltration. Infiltration is generally a significant component of both cooling and heating loads. Refer to Chapter 16 for a detailed discussion of residential air leakage. The simplified residential models found in that chapter can be used to calculate infiltration rates for load calculations. Infiltration should be evaluated for the entire building, not individual rooms or zones.

Natural infiltration leakage rates are modified by mechanical pressurization caused by unbalanced ventilation or duct leakage. These effects are discussed in the section on Combined Ventilation and Infiltration Airflow.

Leakage rate. Air leakage rates are specified either as airflow rate Q_i, or air exchanges per hour (ACH), related as follows:

$$Q_i = \text{ACH}(V/3.6) \tag{6}$$

$$\text{ACH} = \frac{3.6Q_i}{V} \tag{7}$$

where

Q_i = infiltration airflow rate, L/s
ACH = air exchange rate, changes/h
V = building volume, m³

Infiltration airflow rate depends on two factors:

- Building effective leakage area (envelope leaks plus other air leakage paths, notably flues) and its distribution among ceilings, walls, floors, and flues.
- Driving pressure caused by buoyancy (stack effect) and wind.

Using the simplifying assumptions presented in Chapter 16, these factors can be evaluated separately and combined using Equation (8).

$$Q_i = A_L \text{IDF} \tag{8}$$

where

A_L = building effective leakage area (including flue) at reference pressure difference = 4 Pa, assuming discharge coefficient $C_D = 1$, cm²
IDF = infiltration driving force, L/(s·cm²)

The following sections provide procedures for determining A_L and IDF.

Leakage area. As discussed in Chapter 16, there are several interconvertible ways to characterize building leakage, depending on reference pressure differences and assumed discharge coefficient. This formulation uses the effective leakage area at 4 Pa, assuming $C_D = 1$, designated A_L (Sherman and Grimsrud 1980).

The only accurate procedure for determining A_L is by measurement using a pressurization test (commonly called a blower door

Licensed for single user. © 2021 ASHRAE, Inc.

test). Numerous field studies have shown that visual inspection is not adequate for obtaining even a crude estimate of leakage.

For buildings in design, a pressurization test is not possible and leakage area must be assumed for design purposes. Leakage can be estimated using tabulated component leakage areas found in Chapter 16. A simpler approach is based on an assumed average leakage per unit of building surface area:

$$A_L = A_{es} A_{ul} \tag{9}$$

where

A_{es} = building exposed surface area, m²
A_{ul} = unit leakage area, cm²/m² (from Table 3)

A_{ul} is the leakage area per unit surface area; suitable design values are found in Table 3. Field experience indicates that the level of care applied to reducing leakage often depends on winter conditions, because cold-air leakage is readily detected. Thus, lower A_{ul} values are expected in colder climates. Note that the A_{ul} value doubles at each reduced construction quality step in Table 3; very high infiltration loads are typical in older houses.

In Equation (9), A_{es} is the total building surface area at the envelope pressure boundary, defined as all above-grade surface area that separates the outdoors from conditioned or semiconditioned space. Table 4 provides guidance for evaluating A_{es}.

IDF. To determine IDF, use the Chapter 16 methods cited previously. As a further simplification, Barnaby and Spitler (2005) derived the following relationship that yields results approximately equal to the AIM-2 model (Walker and Wilson 1990, 1998; Chapter 16's enhanced model) at design conditions:

$$\text{IDF} = \frac{I_0 + H|\Delta t|[I_1 + I_2(A_{L,flue}/A_L)]}{1000} \tag{10}$$

where

I_0, I_1, I_2 = coefficients, as follows:

	Cooling 3.4 m/s	Heating 6.7 m/s
I_0	25	51
I_1	0.38	0.35
I_2	0.12	0.23

H = building average stack height, m (typically 2.5 m per story)

Table 3 Unit Leakage Areas

Construction	Description	A_{ul}, cm²/m²
Tight	Construction supervised by air-sealing specialist	0.7
Good	Carefully sealed construction by knowledgeable builder	1.4
Average	Typical current production housing	2.8
Leaky	Typical pre-1970 houses	5.6
Very leaky	Old houses in original condition	10.4

Table 4 Evaluation of Exposed Surface Area

Situation	Include	Exclude
Ceiling/roof combination (e.g., cathedral ceiling without attic)	Gross surface area	
Ceiling or wall adjacent to attic	Ceiling or wall area	Roof area
Wall exposed to ambient	Gross wall area (including fenestration area)	
Wall adjacent to unconditioned buffer space (e.g., garage or porch)	Common wall area	Exterior wall area
Floor over open or vented crawlspace	Floor area	Crawlspace wall area
Floor over sealed crawlspace	Crawlspace wall area	Floor area
Floor over conditioned or semiconditioned basement	Above-grade basement wall area	Floor area
Slab floor		Slab area

Δt = difference between indoor and outdoor temperatures, K
$A_{L,flue}$ = flue effective leakage area at reference pressure difference = 4 Pa, assuming $C_D = 1$, cm² (total for flues serving furnaces, domestic water heaters, fireplaces, or other vented equipment, evaluated assuming associated equipment is not operating and with dampers in closed position; see Chapter 16)

Building stack height H is the average height difference between the ceiling and floor (or grade, if the floor is below grade). Thus, for buildings with vented crawlspaces, the crawlspace height is not included. For basement or slab-on-grade construction, H is the average height of the ceiling above grade. Generally, there is significant leakage between basements and spaces above, so above-grade basement height should be included whether or not the basement is fully conditioned. With suitable adjustments for grade level, H can also be estimated as V/A_{cf} (conditioned floor area).

Equation (10) is valid for typical suburban residential wind sheltering, $A_{L,flue} < A_L/2$, and at any elevation. Table 5 shows IDF values derived with Equation (10), assuming $A_{L,flue} = 0$.

Verification of leakage. A postconstruction pressurization test is strongly recommended to verify that design leakage assumptions are actually achieved. Excess leaks should be located and repaired.

Allocation of infiltration to rooms. Total building infiltration should typically be allocated to rooms according to room volume; that is, it should be assumed that each room has the same air exchange rate as the whole building. In reality, leakage varies by room and over time, depending on outdoor temperature and wind conditions. These effects can either increase or decrease room leakage. In addition, system air mixing tends to redistribute localized leakage to all rooms. Thus, in most cases, there is no reasonable way to assign more or less leakage to specific rooms.

An exception is leaky, multistory houses. The preferable and cost-effective response is mitigation of the leakage. If repair is not possible, then for heating load calculation purposes, some leakage can be differentially assigned to lower story and/or windward rooms in proportion to exposed surface area (i.e., adjustment using an "exposure factor").

Multifamily buildings. Usually, the simplified methods in Chapter 16 and this section do not apply to multifamily residences. However, they can be used for row houses that are full building height and have more than one exposed façade. For apartment units subdivided within a former detached residence, the entire building should be analyzed and the resulting exchange rate applied to the apartment volume. In other multifamily structures, infiltration is determined by many factors, including overall building height and degree of sealing between apartments. For low-rise construction, an upper bound for the infiltration rate can be found by evaluating the entire building. As building height increases, leakage problems can be magnified, as discussed in Chapter 16. Estimating leakage rates may require advice from a high-rise infiltration specialist.

Ventilation.

Whole-building ventilation. Because of energy efficiency concerns, residential construction has become significantly tighter over

Table 5 Typical IDF Values, L/(s·cm²)

Licensed for single user. © 2021 ASHRAE, Inc.

the last several decades. Natural leakage rates are often insufficient to maintain acceptable indoor air quality. ASHRAE *Standard* 62.2 specifies the required minimum whole-building ventilation rate as

$$Q_v = 0.15A_{cf} + 3.5(N_{br} + 1) \quad (11)$$

where

Q_v = required ventilation flow rate, L/s
A_{cf} = building conditioned floor area, m^2
N_{br} = number of bedrooms (not less than 1)

Certain mild climates are exempted from this standard; local building authorities ultimately dictate actual requirements. In addition, *Standard* 62.2 specifies alternative methods for determining ventilation requirements that may result in smaller Q_v values. Whole-building ventilation is expected to become more common because of a combination of regulation and consumer demand. The load effect of Q_v must be included in both cooling and heating calculations.

Heat recovery. Heat recovery devices should be considered part of mechanical ventilation systems. These appliances are variously called heat recovery ventilators (HRVs) or energy recovery ventilators (ERVs) and integrate with residential distribution systems, as described in Chapter 26 of the 2020 *ASHRAE Handbook—HVAC Systems and Equipment*. Either sensible heat or total heat (enthalpy) can be exchanged between the exhaust and intake airstreams. ERV/HRV units are characterized by their sensible and total effectiveness.

Local mechanical exhaust. Kitchen and bathroom exhaust fans are required by *Standard* 62.2 and are typically present. Exhaust fans that operate intermittently by manual control are generally not included in load calculations. Continuously operating ventilation should be included. Note that exhaust fans induce load only through enhanced infiltration because of building depressurization (see the section on Combined Ventilation and Infiltration Airflow for further discussion).

Combustion Air. Fuel-fired boilers, furnaces, and domestic water heaters require combustion air. If the combustion air source is within the building envelope (including in semiconditioned basements), additional infiltration and heating load are induced. Locating the equipment outside of conditioned space (e.g., in a garage or vented mechanical closet) or using sealed-combustion equipment eliminates this load.

Combustion air requirements for new forced-draft equipment can be estimated at 0.4 L/(s·kW) or about 12 L/s for a 30 kW heating appliance. The requirements for existing natural draft equipment should be estimated at twice that amount. In many cases, these quantities are relatively small and can be neglected.

For cooling load calculations, heating equipment is assumed to be not operating, leaving only any domestic water heaters, for which the combustion air requirements are generally neglected.

Combined Ventilation and Infiltration Airflow. Mechanical pressurization modifies the infiltration leakage rate. To assess this effect, overall supply and exhaust flow rates must be determined and then divided into "balanced" and "unbalanced" components.

$$Q_{bal} = \min(Q_{sup}, Q_{exh}) \quad (12)$$

$$Q_{unbal} = \max(Q_{sup}, Q_{exh}) - Q_{bal} \quad (13)$$

where

Q_{bal} = balanced airflow rate, L/s
Q_{sup} = total ventilation supply airflow rate, L/s
Q_{exh} = total ventilation exhaust airflow rate (including any combustion air requirements), L/s
Q_{unbal} = unbalanced airflow rate, L/s

Note that unbalanced duct leakage can produce additional pressurization or depressurization. This effect is discussed in the section on Distribution Losses.

Airflow components can be combined with infiltration leakage as follows (Palmiter and Bond 1991; Sherman 1992):

$$Q_{vi} = \max(Q_{unbal}, Q_i + 0.5Q_{unbal}) \quad (14)$$

where

Q_{vi} = combined infiltration/ventilation flow rate (not including balanced component), L/s
Q_i = infiltration leakage rate assuming no mechanical pressurization, L/s

Ventilation/infiltration load. The cooling or heating load from ventilation and infiltration is calculated as follows:

$$q_{vi,s} = C_s[Q_{vi} + (1 - \varepsilon_s)Q_{bal,hr} + Q_{bal,oth}]\Delta t \quad (15)$$

$$q_{vi,l} = C_l(Q_{vi} + Q_{bal,oth})\Delta W \quad \text{(no HRV/ERV)} \quad (16)$$

$$q_{vi,t} = C_{t6}[Q_{vi} + (1 - \varepsilon_t)Q_{bal,hr} + Q_{bal,oth}]\Delta h \quad (17)$$

$$q_{vi,l} = q_{vi,t} - q_{vi,s} \quad (18)$$

where

$q_{vi,s}$ = sensible ventilation/infiltration load, W
ε_s = HRV/ERV sensible effectiveness
$Q_{bal,hr}$ = balanced ventilation flow rate via HRV/ERV equipment, L/s
$Q_{bal,oth}$ = other balanced ventilation supply airflow rate, L/s
Δt = indoor/outdoor temperature difference, K
ΔW = indoor/outdoor humidity ratio difference
$q_{vi,t}$ = total ventilation/infiltration load, W
ε_t = HRV/ERV total effectiveness
Δh = indoor/outdoor enthalpy difference, kJ/kg
$q_{vi,l}$ = latent ventilation/infiltration load, W

Distribution Losses. Air leakage and heat losses from duct systems frequently impose substantial equipment loads in excess of building requirements. The magnitude of losses depends on the location of duct runs, their surface areas, surrounding temperatures, duct wall insulation, and duct airtightness. These values are usually difficult to accurately determine at the time of preconstruction load calculations, and must be estimated using assumed values, so that selected equipment capacity is sufficient.

Good design and workmanship both reduce duct losses. In particular, locating duct runs within the conditioned envelope (above dropped hallway ceilings, for example) substantially eliminates duct losses. Specific recommendations are found in Chapter 10 of the 2020 *ASHRAE Handbook—HVAC Systems and Equipment*. Good workmanship and correct materials are essential to achieve low leakage. Many common sealing techniques, notably duct tape, have been shown to fail in a few years. Well-constructed duct systems show leakage rates of 5% of fan flow from supply and return runs, whereas 11% or more on each side is more typical. Because of the potentially large load impact of duct leakage, postconstruction verification of airtightness is strongly recommended.

Duct losses can be estimated using models specified in ASHRAE *Standard* 152, Francisco and Palmiter (1999), and Palmiter and Francisco (1997). The allowance for distribution losses is calculated as follows:

$$q_d = F_{dl}\, q_{bl} \quad (19)$$

where

q_d = distribution loss, W
F_{dl} = duct loss/gain factor, from Table 6 *or* ASHRAE *Standard* 152 design efficiencies *or* a detailed model
q_{bl} = total building load, W

Table 6 shows typical duct loss/gain factors calculated for the conditions indicated. These values can provide guidance for hand

Licensed for single user. © 2021 ASHRAE, Inc.

Values calculated for ASHRAE *Standard* 152 default duct system surface area using model of Francisco and Palmiter (1999). Values are provided as guidance only; losses can differ substantially for other conditions and configurations. Assumed surrounding temperatures:

Cooling (C): $t_o = 35°C$, $t_{attic} = 49°C$, $t_b = 20°C$, $t_{crawl} = 22°C$ Heating/furnace (H/F) and heating/heating pump (H/HP): $t_o = 0°C$, $t_{attic} = 0°C$, $t_b = 18°C$, $t_{crawl} = 0°C$

estimates, and illustrate the need for achieving low duct leakage. To the extent conditions differ from those shown, specific calculations should be made using a method cited previously. Note also that Table 6 cooling factors represent sensible gain only. Duct leakage may also introduce significant latent gain; see ASHRAE *Standard* 152.

7. COOLING LOAD

A cooling load calculation determines total sensible cooling load from heat gain (1) through opaque surfaces (walls, floors, ceilings, and doors), (2) through transparent fenestration surfaces (windows, skylights, and glazed doors), (3) caused by infiltration and ventilation, and (4) because of occupancy. The latent portion of the cooling load is evaluated separately. Although the entire structure may be considered a single zone, equipment selection and system design should be based on room-by-room calculations. For proper design of the distribution system, the conditioned airflow required by each room must be known.

Peak Load Computation

To select a properly sized cooling unit, the peak or maximum load (block load) for each zone must be computed. The block load for a single-family detached house with one central system is the sum of all the room loads. If the house has a separate system for each zone, each zone block load is required. When a house is zoned with one central cooling system, the system size is based on the entire house block load, whereas zone components, such as distribution ducts, are sized using zone block loads.

In multifamily structures, each living unit has a zone load that equals the sum of the room loads. For apartments with separate systems, the block load for each unit establishes the system size. Apartment buildings having a central cooling system with fan-coils in each apartment require a block load calculation for the complete structure to size the central system; each unit load establishes the size of the fan-coil and air distribution system for each apartment. One of the methods for nonresidential buildings discussed in Chapter 18 may be used to calculate the block load.

Opaque Surfaces

Heat gain through walls, floors, ceilings, and doors is caused by (1) the air temperature difference across such surfaces and (2) solar gains incident on the surfaces. The heat capacity of typical construction moderates and delays building heat gain. This effect is modeled in detail in the computerized RHB method, resulting in accurate simultaneous load estimates.

Table 7 Opaque Surface Cooling Factor Coefficients

Surface Type	OF_t	OF_b, K	OF_r
Ceiling or wall adjacent to vented attic	0.62	$14.3\alpha_{roof} - 4.5$	–0.19
Ceiling/roof assembly	1	$38.3\alpha_{roof} - 7.0$	–0.36
Wall (wood frame) or door with solar exposure	1	8.2	–0.36
Wall (wood frame) or door (shaded)	1	0	–0.36
Floor over ambient	1	0	–0.06
Floor over crawlspace	0.33	0	–0.28
Slab floor (see Slab Floor section)			

α_{roof} = roof solar absorptance (see Table 8).

Table 8 Roof Solar Absorptance α_{roof}

	Color			
Material	White	Light	Medium	Dark
Asphalt shingles	0.75	0.75	0.85	0.92
Tile	0.30	0.40	0.80	0.80
Metal	0.35	0.50	0.70	0.90
Elastomeric coating	0.30			

Source: Summarized from Parker et al. (2000).

The RLF method uses the following to estimate cooling load:

$$q_{opq} = A \times CF_{opq} \quad (20)$$

$$CF_{opq} = U(OF_t \Delta t + OF_b + OF_r DR) \quad (21)$$

where

q_{opq} = opaque surface cooling load, W
A = net surface area, m^2
CF = surface cooling factor, W/m^2
U = construction U-factor, $W/(m^2 \cdot K)$
Δt = cooling design temperature difference, K
OF_t, OF_b, OF_r = opaque-surface cooling factors (see Table 7)
DR = cooling daily range, K

OF factors, found in Table 7, represent construction-specific physical characteristics. OF_t values less than 1 capture the buffering effect of attics and crawlspaces, OF_b represents incident solar gain, and OF_r captures heat storage effects by reducing the effective temperature difference. Note also that CF can be viewed as CF = $U \times$ CLTD, the formulation used in prior residential and nonresidential methods.

Table 7 factors for walls are simplified in two ways. First, the values do not depend on wall orientation. This has minimal effect on total load, because residences typically have a mix of exposures.

Licensed for single user. © 2021 ASHRAE, Inc.

Second, only wood frame construction is included. The wood frame values can be used for heavier construction (e.g., masonry), but this overpredicts the wall's contribution to cooling load and is thus conservative.

Slab Floors

Slab floors produce a slight reduction in cooling load, as follows:

$$q_{opq} = A \times \mathrm{CF}_{slab} \quad (22)$$

$$\mathrm{CF}_{slab} = 1.9 - 1.4\, h_{srf} \quad (23)$$

where

A = area of slab, m^2
CF_{slab} = slab cooling factor, W/m^2
h_{srf} = effective surface conductance, including resistance of slab covering material such as carpet $=1/(R_{cvr} + 0.12)$, W/(m^2·K). Representative R_{cvr} values are found in Chapter 6 of the 2020 *ASHRAE Handbook—HVAC Systems and Equipment*.
1.9 = constant, W/m^2
1.4 = factor, K

Surfaces Adjacent to Buffer Space

Heat gain from adjacent unconditioned or semiconditioned spaces can be calculated based on the partition U-factor and temperature difference. Buffer space air temperature t_b can be estimated using procedures discussed in the section on Adjacent Buffer Spaces. Generally, simple approximations are sufficient. If the partition surface is large and/or poorly insulated, buffer temperature should be calculated with more care.

Transparent Fenestration Surfaces

Cooling load associated with nondoor fenestration is calculated as follows:

$$q_{fen} = A \times \mathrm{CF}_{fen} \quad (24)$$

$$\mathrm{CF}_{fen} = U(\Delta t - 0.46\,\mathrm{DR}) + \mathrm{PXI} \times \mathrm{SHGC} \times \mathrm{IAC} \times \mathrm{FF}_s \quad (25)$$

where

q_{fen} = fenestration cooling load, W
A = fenestration area (including frame), m^2
CF_{fen} = surface cooling factor, W/m^2
U = fenestration NFRC *heating* U-factor, W/(m^2·K)
Δt = cooling design temperature difference, K
PXI = peak exterior irradiance, including shading modifications, W/m^2 [see Equations (26) or (27)]
SHGC = fenestration rated or estimated NFRC solar heat gain coefficient
IAC = interior shading attenuation coefficient, Equation (29)
FF_s = fenestration solar load factor, Table 13

Peak Exterior Irradiance (PXI). Although solar gain occurs throughout the day, RP-1199 regression studies (Barnaby et al. 2004) showed that the cooling load contribution of fenestration correlates well with the peak-hour irradiance incident on the fenestration exterior. PXI is calculated as follows:

$$\mathrm{PXI} = T_x E_t \text{ (unshaded fenestration)} \quad (26)$$

$$\mathrm{PXI} = T_x[E_d + (1 - F_{shd})E_D] \text{ (shaded fenestration)} \quad (27)$$

where

PXI = peak exterior irradiance, W/m^2
E_t, E_d, E_D = peak total, diffuse, and direct irradiance (Table 9 or 10), W/m^2
T_x = transmission of exterior attachment (insect screen or shade screen)
F_{shd} = fraction of fenestration shaded by permanent overhangs, fins, or environmental obstacles

Table 9 Peak Irradiance Equations

Horizontal surfaces

$$E_t = 816.2 + 10.20L - 0.1806L^2$$

$$E_d = \min(E_t, 170)$$

$$E_D = E_t - E_d$$

Vertical surfaces

$$\phi = \left|\frac{\psi}{180}\right| \text{ (normalized exposure, 0 – 1)}$$

$$E_t = 423.5 + 1240\phi - 5143\phi^3 + 3191\phi^4 + 35.25\phi L + 0.1427\phi L^2 - 12.89L - 0.6172L^2 + [0.7802L^2/(\phi + 1)]$$

$$E_d = \min\left(356.3 - 37.73\phi^2 + 0.3022\phi L - \frac{115.9\sqrt[4]{L}}{\phi + 1}\right)$$

$$E_D = E_t - E_d$$

where

E_t, E_d, E_D = peak hourly total, diffuse, and direct irradiance, W/m^2
L = site latitude, °N
ψ = exposure (surface azimuth), ° from south (–180 to +180)

Table 10 Peak Irradiance, W/m^2

	E_d	193	187	182	178	174	170	167	164	193
	E_t	492	542	589	632	673	710	744	775	492
South	E_D	21	114	203	286	365	439	509	574	21
	E_d	197	192	188	185	182	180	177	175	197
	E_t	218	306	391	471	547	619	686	749	218
Horizontal	E_D	788	790	782	765	739	705	661	608	788
	E_d	170	170	170	170	170	170	170	170	170
	E_t	958	960	952	935	909	875	831	778	958

For horizontal or vertical surfaces, peak irradiance values can be obtained from Table 10 for primary exposures, or from Table 9 equations for any exposure. Skylights with slope less than 30° from horizontal should be treated as horizontal. Steeper, nonvertical slopes are not supported by the RLF method.

Exterior Attachments. Common window coverings can significantly reduce fenestration solar gain. Table 11 shows transmission values for typical attachments.

Permanent Shading. The shaded fraction F_{shd} can be taken as 1 for any fenestration shaded by adjacent structures during peak hours. Simple overhang shading can be estimated using the following:

$$F_{shd} = \min\left[1, \max\left(0, \frac{\mathrm{SLF} \times D_{oh} - X_{oh}}{h}\right)\right] \quad (28)$$

where

SLF = shade line factor from Table 12
D_{oh} = depth of overhang (from plane of fenestration), m
X_{oh} = vertical distance from top of fenestration to overhang, m
h = height of fenestration, m

Licensed for single user. © 2021 ASHRAE, Inc.

The shade line factor (SLF) is the ratio of the vertical distance a shadow falls beneath the edge of an overhang to the depth of the overhang, so the shade line equals the SLF times the overhang depth. Table 12 shows SLFs for July 21 averaged over the hours of greatest solar intensity on each exposure.

More complex shading situations should be analyzed with the RHB method.

Fenestration Solar Load Factors. Fenestration solar load factors FF_s depend on fenestration exposure and are found in Table 13. The values represent the fraction of transmitted solar gain that contributes to peak cooling load. It is thus understandable that morning (east) values are lower than afternoon (west) values. Higher values are included for multifamily buildings with limited exposure.

Interior Shading. Interior shading significantly reduces solar gain and is ubiquitous in residential buildings. Field studies show that a large fraction of windows feature some sort of shading; for example, James et al. (1997) studied 368 houses and found interior shading in 80% of audited windows. Therefore, in all but special circumstances, interior shading should be assumed when calculating cooling loads. In the RLF method, the interior attenuation coefficient (IAC) model is used, as described in Chapter 15. Residential values from that chapter are consolidated in Table 14. IAC values for many other configurations are found in Chapter 15, Tables 14A to 14G.

In some cases, it is reasonable to assume that a shade is partially open. For example, drapes are often partially open to admit daylight. IAC values are computed as follows:

$$IAC = 1 + F_{cl}(IAC_{cl} - 1) \quad (29)$$

where

IAC = interior attenuation coefficient of fenestration with partially closed shade
F_{cl} = shade fraction closed (0 to 1)
IAC_{cl} = interior attenuation coefficient of fully closed configuration (from Table 14 or Chapter 15, Tables 14A to 14G)

Table 11 Exterior Attachment Transmission

Attachment	T_x
None	1.0
Exterior insect screen	0.64 (see Chapter 15, Table 13G)
Shade screen	Manufacturer shading coefficient (SC) value, typically 0.4 to 0.6

Table 12 Shade Line Factors (SLFs)

Infiltration and Ventilation

See the Common Data and Procedures section.

Internal Gain

The contributions of occupants, lighting, and appliance gains to peak sensible and latent loads can be estimated as

$$q_{ig,s} = 136 + 2.2A_{cf} + 22N_{oc} \quad (30)$$

$$q_{ig,l} = 20 + 0.22A_{cf} + 12N_{oc} \quad (31)$$

where

$q_{ig,s}$ = sensible cooling load from internal gains, W
$q_{ig,l}$ = latent cooling load from internal gains, W
A_{cf} = conditioned floor area of building, m^2
N_{oc} = number of occupants (if unknown, estimate as $N_{br} + 1$)

Equations (30) and (31) and their coefficients are derived from Building America (2004) load profiles evaluated at 4:00 PM, as documented by Barnaby and Spitler (2005). Predicted gains are typical for U.S. homes. Further allowances should be considered when unusual lighting intensities or other equipment are in continuous use during peak cooling hours. In critical situations where intermittent high occupant density or other internal gains are expected, a parallel cooling system should be considered.

For room-by-room calculations, $q_{ig,s}$ should be evaluated for the entire conditioned area, and allocated to kitchen and living spaces.

Air Distribution System: Heat Gain

See the Common Data and Procedures section.

Total Latent Load

The latent cooling load is the result of three predominant moisture sources: outdoor air (infiltration and ventilation), occupants, and miscellaneous sources, such as cooking, laundry, and bathing. These components, discussed in previous sections, combine to yield the total latent load:

$$q_l = q_{vi,l} + q_{ig,l} \quad (32)$$

where

q_l = total latent load, W

Table 14 Interior Attenuation Coefficients (IAC_{cl})

		Drapes			Roller Shades			Blinds	
		Open-Weave	Closed-Weave		Opaque		Translucent

$q_{vi,l}$ = ventilation/infiltration latent gain, W, from Equation (16) or (18)
$q_{ig,l}$ = internal latent gain, W, from Equation (31)

Additional latent gains may be introduced through return duct leakage and specific atypical sources. These may be estimated and included. Lstiburek and Carmody (1993) provide data for household moisture sources; however, again note that Equation (31) adequately accounts for normal gains.

Because air conditioning systems are usually controlled by a thermostat, latent cooling is a side effect of equipment operation. During periods of significant latent gain but mild temperatures, there is little cooling operation, resulting in unacceptable indoor humidity. Multispeed equipment, combined temperature/humidity control, and dedicated dehumidification should be considered to address this condition.

Summary of RLF Cooling Load Equations

Table 15 contains a brief list of equations used in the cooling load calculation procedure described in this chapter.

8. HEATING LOAD

Calculating a residential heating load involves estimating the maximum heat loss of each room or space to be heated and the simultaneous maximum (block) heat loss for the building, while maintaining a selected indoor air temperature during periods of design outdoor weather conditions. As discussed in the section on Calculation Approach, heating calculations use conservative assumptions, ignoring solar and internal gains, and building heat storage. This leaves a simple steady-state heat loss calculation, with the only significant difficulty being surfaces adjacent to grade.

Exterior Surfaces Above Grade

All above-grade surfaces exposed to outdoor conditions (walls, doors, ceilings, fenestration, and raised floors) are treated identically, as follows:

$$q = A \times \mathrm{HF} \tag{33}$$

$$\mathrm{HF} = U\Delta t \tag{34}$$

where HF is the heating load factor in W/m^2.

Two ceiling configurations are common:

- For **ceiling/roof combinations** (e.g., flat roof or cathedral ceiling), the U-factor should be evaluated for the entire assembly.
- For **well-insulated ceilings (or walls) adjacent to vented attic space**, the U-factor should be that of the insulated assembly only (the roof is omitted) and the attic temperature assumed to equal the heating design outdoor temperature. The effect of attic radiant barriers can be neglected. In cases where the ceiling or wall is not well insulated, the adjacent buffer space procedure (see the section on Surfaces Adjacent to Buffer Space) can be used.

Below-Grade and On-Grade Surfaces

The Heating Load Calculations section of Chapter 18 includes simplified procedures for estimating heat loss through below-grade walls and below- and on-grade floors. Those procedures are applicable to residential buildings. In more detailed work, Bahnfleth and Pedersen (1990) show a significant effect of the area-to-perimeter ratio. For additional generality and accuracy, see also methods described or cited in Beausoleil-Morrison and Mitalas (1997), CAN/CSA *Standard* F280, HRAI (2014), and Krarti and Choi (1996).

Surfaces Adjacent to Buffer Space

Heat loss to adjacent unconditioned or semiconditioned spaces can be calculated using a heating factor based on the partition temperature difference:

$$\mathrm{HF} = U(t_i - t_b) \tag{35}$$

Buffer space air temperature t_b can be estimated using procedures discussed in the section on Adjacent Buffer Spaces. Generally, simple approximations are sufficient except where the partition surface is poorly insulated.

Crawlspaces and basements are cases where the partition (the house floor) is often poorly insulated; they also involve heat transfer to the ground. Most codes require crawlspaces to be adequately vented year round. However, work highlighting problems with venting crawlspaces (DeWitt 2003) has led to application of sealed crawlspaces with insulated perimeter walls. Equation (5) may be applied to basements and crawlspace by including appropriate ground-related terms in the heat balance formulation. For example, when including below-grade walls, $A_x = A_{bw}$, $U_x = U_{avg,bw}$, and $t_x = t_{gr}$ should be included as applicable in the summations in Equation (5). Losses from piping or ducting should be included as additional buffer space heat gain. Determining the ventilation or infiltration rate for crawlspaces and basements is difficult. Latta and Boileau (1969) estimated the air exchange rate for an uninsulated basement at 0.67 ach under winter conditions. Field measurements of eight ventilated crawlspaces summarized in Palmiter and Francisco (1996) yielded a median flow rate of 4.6 ach. Clearly, crawlspace infiltration rates vary widely, depending on vent configuration and operation.

Ventilation and Infiltration

Infiltration of outdoor air causes both sensible and latent heat loss. The energy required to raise the temperature of outdoor infiltrating air to indoor air temperature is the sensible component; energy associated with net loss of moisture from the space is the latent component. Determining the volumetric flow Q of outdoor air

Table 15 Summary of RLF Cooling Load Equations

Load Source	Equation	Tables and Notes
Exterior opaque surfaces	$q_{opq} = A \times \mathrm{CF}$	
	$\mathrm{CF} = U(\mathrm{OF}_t\Delta t + \mathrm{OF}_b + \mathrm{OF}_r\mathrm{DR})$	OF factors from Table 7
Exterior transparent surfaces	$q_{fen} = A \times \mathrm{CF}$	PXI from Table 9 or 10 plus adjustments
	$\mathrm{CF} = U(\Delta t - 0.46\mathrm{DR}) + \mathrm{PXI} \times \mathrm{SHGC} \times \mathrm{IAC} \times \mathrm{FF}_s$	FF_s from Table 13
Partitions to unconditioned space	$q = AU\Delta t$	Δt = temperature difference across partition
Ventilation/infiltration	$q_s = C_s Q\Delta t$	See Common Data and Procedures section
Occupants and appliances	$q_{ig,s} = 136 + 2.2A_{cf} + 22N_{oc}$	
Distribution	$q_d = F_{dl}\Sigma q$	F_{dl} from Table 6
Total sensible load	$q_s = q_d + \Sigma q$	
Latent load	$q_l = q_{vi,l} + q_{ig,l}$	
Ventilation/infiltration	$q_{vi,l} = C_l Q\Delta W$	
Internal gain	$q_{ig,l} = 20 + 0.22A_{cf} + 12N_{oc}$	

Licensed for single user. © 2021 ASHRAE, Inc.

entering the building is discussed in the Common Data and Procedures section and in Chapter 16. Determining the resulting sensible and latent loads is discussed in the Ventilation/Infiltration Load subsection.

Humidification

In many climates, humidification is required to maintain comfortable indoor relative humidity under heating conditions. The latent ventilation and infiltration load calculated, assuming desired indoor humidity conditions, equals the sensible heat needed to evaporate water at a rate sufficient to balance moisture losses from air leakage. Self-contained humidifiers provide this heat from internal sources. If the heat of evaporation is taken from occupied space or the distribution system, the heating capacity should be increased accordingly.

Pickup Load

For intermittently heated buildings and night thermostat setback, additional heat is required to raise the temperature of air, building materials, and material contents to the specified temperature. The rate at which this additional heat must be supplied is the pickup load, which depends on the structure's heat capacity, its material contents, and the time in which these are to be heated.

Because the design outdoor temperature is generally much lower than typical winter temperatures, under most conditions excess heating capacity is available for pickup. Therefore, many engineers make no pickup allowance except for demanding situations. If pickup capacity is justified, the following guidance can be used to estimate the requirement.

Relatively little rigorous information on pickup load exists. Building simulation programs can predict recovery times and required equipment capacities, but a detailed simulation study is rarely practical. Armstrong et al. (1992a, 1992b) developed a model for predicting recovery from setback and validated it for a church and two office buildings. Nelson and MacArthur (1978) studied the relationship between thermostat setback, furnace capacity, and recovery time. Hedrick et al. (1992) compared Nelson and MacArthur's results to tests for two test houses and found that the furnace oversizing required for a 2 h recovery time ranges from 20 to 120%, depending on size of setback, building mass, and heating Δt (colder locations require less oversizing on a percentage basis).

The designer should be aware that there are trade-offs between energy savings from thermostat setback and energy penalties incurred by oversizing equipment. Koenig (1978) studied a range of locations and suggested that 30% oversizing allows recovery times less than 4 h for nearly the entire heating season and is close to optimum from an energy standpoint.

The preceding guidance applies to residential buildings with fuel-fired furnaces. Additional considerations may be important for other types of heating systems. For air-source heat pumps with electric resistance auxiliary heat, thermostat setback may be undesirable (Bullock 1978).

Thermostats with optimum-start algorithms, designed to allow both energy savings and timely recovery to the daytime set point, are becoming routinely available and should be considered in all cases.

Summary of Heating Load Procedures

Table 16 lists equations used in the heating load calculation procedures described in this chapter.

9. LOAD CALCULATION EXAMPLE

A single-family detached house with floor plan shown in Figure 1 is located in Atlanta, GA, USA. Construction characteristics are documented in Table 17. Using the RLF method, find the block (whole-house) design cooling and heating loads. A furnace/air-conditioner forced-air system is planned with a well-sealed and well-insulated (R-8 wrap) attic duct system.

Solution

Design Conditions. Table 18 summarizes design conditions. Typical indoor conditions are assumed. Outdoor conditions are determined from Chapter 14.

Table 16 Summary of Heating Load Calculation Equations

Load Source	Equation	Tables and Notes
Exterior surfaces above grade	$q = UA\Delta t$	$\Delta t = t_i - t_o$
Partitions to unconditioned buffer space	$q = UA\Delta t$	Δt = temp. difference across partition
Walls below grade	$q = U_{avg,bw}A(t_{in} - t_{gr})$	
Floors on grade	$q = F_p p\Delta t$	See Chapter 18, Equations (41) and (42)
Floors below grade	$q = U_{avg,bf}A(t_{in} - t_{gr})$	See Chapter 18, Equations (37) and (38)
Ventilation/infiltration	$q_{vi} = C_s Q\Delta t$	From Common Data and Procedures section
Total sensible load	$q_s = \Sigma q$	

Table 17 Example House Characteristics

Component	Description	Factors
Roof/ceiling	Flat wood frame ceiling (insulated with R-5.3 fiberglass) beneath vented attic with medium asphalt shingle roof	U = 0.18 W/(m²·K) α_{roof} = 0.85 (Table 8)
Exterior walls	Wood frame, exterior wood sheathing, interior gypsum board, R-2.3 fiberglass insulation	U = 51 W/(m²·K)
Doors	Wood, solid core	U = 2.3 W/(m²·K)
Floor	Slab on grade with heavy carpet over rubber pad; R-0.9 edge insulation to 1 m below grade	R_{cvr} = 0.21 (m²·K)/W (Table 3, Chapter 6, 2020 *ASHRAE Handbook—HVAC Systems and Equipment*) F_p = 85 W/(m²·K) (estimated from Chapter 18, Table 24)
Windows	Low-e/low-solar in wood frames. Half fixed, half operable with insect screens (except living room picture window, which is fixed). 0.6 m eave overhang on east and west with eave edge at same height as top of glazing for all windows. Allow for typical closed-weave light drape interior shading, half closed.	Fixed: U = 2.01 W/(m²·K); SHGC = 0.36 (Table 2) Operable: U = 2.21 W/(m²·K); SHGC = 0.31 (Table 2); T_x = 0.64 (Table 11) IAC_{cl} = 0.68 (Table 14)
Construction	Good	A_{tl} = 1.4 cm²/m² (Table 3)

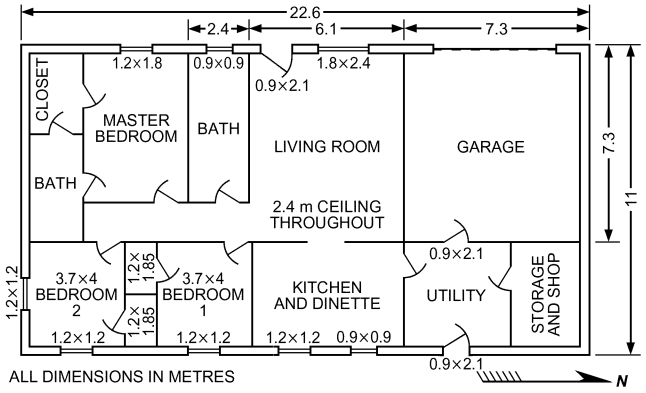

Fig. 1 Example House

Component Quantities. Areas and lengths required for load calculations are derived from plan dimensions (Figure 1). Table 19 summarizes these quantities.

Opaque Surface Factors. Heating and cooling factors are derived for each component condition. Table 20 shows the resulting factors and their sources.

Window Factors. Deriving cooling factors for windows requires identifying all unique glazing configurations in the house. Equation (25) input items indicate that the variations for this case are exposure, window height (with overhang shading), and frame type (which determines U-factor, SHGC, and the presence of insect screen). CF derivation for all configurations is summarized in Table 21.

For example, CF for operable 1 m high windows facing west (the second row in Table 21) is derived as follows:

- U-factor and SHGC are found in Table 2.
- Each operable window is equipped with an insect screen. From Table 11, $T_x = 0.64$ for this arrangement.
- Overhang shading is evaluated with Equation (28). For west exposure and latitude 34°, Table 12 shows SLF = 1.1. Overhang depth (D_{oh}) is 0.6 m and the window-overhang distance (X_{oh}) is 0 m. With window height h of 0.9 m, $F_s = 0.73$ (73% shaded).
- PXI depends on peak irradiance and shading. Approximating site latitude as 35°N, Table 10 shows $E_D = 570$ and $E_d = 164$ W/m^2 for west exposure. Equation (27) combines these values with T_x and F_s to find PXI = 0.64[164 + (1 – 0.73)570] = 203 W/m^2.
- All windows are assumed to have some sort of interior shading in the half-closed position. Use Equation (29) with $F_{cl} = 0.5$ and IAC$_{cl}$ = 0.68 (per Table 17) to derive IAC = 0.84.
- FF$_s$ is taken from Table 13 for west exposure.
- Finally, inserting the preceding values into Equation (25) gives CF = 2.21(9.1 – 0.46 × 9.3) + 203 × 0.31 × 0.84 × 0.56 = 40.3 W/m^2.

Table 19 Example House Component Quantities

Component	Quantity	Notes
Ceiling	195.3 m^2	Overall area less garage area (22.6 × 11) – (7.3 × 7.3)
Doors	3.8 m^2	2 (each 0.9 by 2.1 m)
Windows	13.9 m^2	
Walls, exposed exterior	126.2 m^2 gross, 108.5 m^2 net	Wall height = 2.4 m
Walls, garage	35.0 m^2	
Floor area	195.3 m^2	
Floor perimeter	67.2 m	Include perimeter adjacent to garage
Total exposed surface	67.2 m^2	Wall gross area (including garage wall) plus ceiling area
Volume	356.5 m^3	

Envelope Loads. Given the load factors and component quantities, heating and cooling loads are calculated for each envelope element, as shown in Table 22.

Infiltration and Ventilation. From Table 3, A_{ul} for this house is 1.4 cm^2/m^2 of exposed surface area. Applying Equation (9) yields $A_L = A_{es} \times A_{ul} = 356.5 \times 1.4 = 499$ cm^2. Using Table 5, estimate heating and cooling IDF to be 0.073 and 0.035 (L·s)/cm^2, respectively [alternatively, Equation (10) could be used to find IDF values]. Apply Equation (8) to find the infiltration leakage rates and Equation (7) to convert the rate to air changes per hour:

$$Q_{i,h} = 499 \times 0.073 = 36 \text{ L/s (0.28 ach)}$$

$$Q_{i,c} = 499 \times 0.035 = 17 \text{ L/s (0.13 ach)}$$

Calculate the ventilation outdoor air requirement with Equation (11) using $A_{cf} = 195.3$ m^2 and $N_{br} = 3$, resulting in $Q_v = 43$ L/s. For design purposes, assume that this requirement is met by a mechanical system with balanced supply and exhaust flow rates ($Q_{unbal} = 0$).

Find the combined infiltration/ventilation flow rates by summing the balanced ventilation flow with net infiltration flow derived with Equation (14):

$$Q_{vi,h} = 43 + \max(0, 36 + 0.5 \times 0) = 79 \text{ L/s}$$

$$Q_{vi,c} = 43 + \max(0, 17 + 0.5 \times 0) = 60 \text{ L/s}$$

At Atlanta's elevation of 313 m, elevation adjustment of heat factors results in a small (4%) reduction in air heat transfer; thus, adjustment is unnecessary, resulting in $C_s = 23$ W/(L·s·K). Use Equation (15) with $Q_{bal,hr} = 0$ and $Q_{bal,oth} = 0$ to calculate the sensible infiltration/ventilation loads:

$$q_{vi,s,h} = 1.23 \times 79 \times 23 = 2235 \text{ W}$$

$$q_{vi,s,c} = 1.23 \times 60 \times 9.1 = 672 \text{ W}$$

Table 23 Example House Total Sensible Loads

Item	Heating Load, W	Cooling Load, W
Envelope	4674	1900
Infiltration/ventilation	2235	672
Internal gain		654
Subtotal	6909	3225
Distribution loss	898	871
Total sensible load	7807	4096

Internal Gain. Apply Equation (30) to find the sensible cooling load from internal gain:

$$q_{ig,s} = 136 + 2.2 \times 195.3 + 22(3 + 1) = 654 \text{ W}$$

Distribution Losses and Total Sensible Load. Table 23 summarizes the sensible load components. Distribution loss factors F_{dl} are estimated (from Table 6) at 0.13 for heating and 0.27 for cooling.

Latent Load. Use Equation (16) with C_l = 3010 W/(L·s), $Q_{vi,c}$ = 60 L/s, $Q_{bal,oth}$ = 0, and ΔW = 0.0050 to calculate the infiltration/ventilation latent load = 903 W. Use Equation (31) to find the latent load from internal gains = 111 W. Therefore, the total latent cooling load is 752 W.

10. SYMBOLS

A = area, m²; ground surface temperature amplitude, °C
A_L = building effective leakage area (including flue) at 4 Pa, assuming C_D = 1, cm²
C_l = air latent heat factor, 3010 W/(L·s) at sea level
C_s = air sensible heat factor, 23 W/(L·s·K) at sea level
C_t = air total heat factor, 1.2 W/(L·s) (kJ/kg) at sea level
CF = cooling load factor, W/m²
D_{oh} = depth of overhang (from plane of fenestration), m
DR = daily range of outdoor dry-bulb temperature, K
E = peak irradiance for exposure, W/m²
F_{dl} = distribution loss factor
F_p = heat loss coefficient per unit length of perimeter, W/(m·K)
F_{shd} = shaded fraction
FF = coefficient for CF_{fen}
G = internal gain coefficient
h_{srf} = effective surface conductance, including resistance of slab covering material such as carpet, $1/(R_{cvr} + 0.12)$ W/(m²·K)
Δh = indoor/outdoor enthalpy difference, kJ/kg
H = height, m
HF = heating (load) factor, W/m²
I = infiltration coefficient
IAC = interior shading attenuation coefficient
IDF = infiltration driving force, L/(s·cm²)

Licensed for single user. © 2021 ASHRAE, Inc.

k = conductivity, W/(m·K)
LF = load factor, W/m^2
OF = coefficient for CF_{opq}
p = perimeter or exposed edge of floor, m
PXI = peak exterior irradiance, including shading modifications, W/m^2
q = heating or cooling load, W
Q = air volumetric flow rate, L/s
R = insulation thermal resistance, (m^2·K)/W
SHGC = fenestration rated or estimated NFRC solar heat gain coefficient
SLF = shade line factor
t = temperature, °C
T_x = solar transmission of exterior attachment
Δt = design dry-bulb temperature difference (cooling or heating), K
U = construction U-factor, W/(m^2·K) (for fenestration, NFRC rated *heating* U-factor)
w = width, m
ΔW = indoor-outdoor humidity ratio difference, kg_w/kg_{da}
V = building volume, m^3
X_{oh} = vertical distance from top of fenestration to overhang, m
z = depth below grade, m
α_{roof} = roof solar absorptance
ε = heat/energy recovery ventilation (HRV/ERV) effectiveness

Subscripts

avg = average
b = base (as in OF_b), basement, building, buffer
bal = balanced
bf = basement floor
bl = building load
bw = basement wall
br = bedrooms
ceil = ceiling
cf = conditioned floor
cl = closed
cvr = floor covering
d = diffuse, distribution
D = direct
da = dry air
dl = distribution loss
env = envelope
es = exposed surface
exh = exhaust
fen = fenestration
floor = floor
gr = ground
hr = heat recovery
i = infiltration
in = indoor
ig = internal gain
l = latent
o = outdoor
oc = occupant
oh = overhang
opq = opaque
oth = other
pf = projected product
r = daily range (as in OF_r)
rhb = calculated with RHB method
s = sensible or solar
shd = shaded
slab = slab
srf = surface
sup = supply
t = total or temperature (as in OF_t)
ul = unit leakage
unbal = unbalanced
v = ventilation
vi = ventilation/infiltration
w = water
wall = wall
x = *x*th buffer space surface

Example Cooling and Heating Load Calculations 18.44
Previous Cooling Load Calculation Methods 18.57
Building Example Drawings 18.61

HEATING and cooling load calculations are the primary design basis for most heating and air-conditioning systems and components. These calculations affect the size of piping, ductwork, diffusers, air handlers, boilers, chillers, coils, compressors, fans, and every other component of systems that condition indoor environments. Cooling and heating load calculations can significantly affect first cost of building construction, comfort and productivity of occupants, and operating cost and energy consumption.

Simply put, heating and cooling loads are the rates of energy input (heating) or removal (cooling) required to maintain an indoor environment at a desired temperature and humidity condition. Heating and air conditioning systems are designed, sized, and controlled to accomplish that energy transfer. The amount of heating or cooling required at any particular time varies widely, depending on external (e.g., outdoor temperature) and internal (e.g., number of people occupying a space) factors.

Peak design heating and cooling load calculations, which are this chapter's focus, seek to determine the maximum rate of heating and cooling energy transfer needed at any point in time. Similar principles, but with different assumptions, data, and application, can be used to estimate building energy consumption, as described in Chapter 19.

This chapter discusses common elements of cooling load calculation (e.g., internal heat gain, ventilation and infiltration, moisture migration, fenestration heat gain) and two methods of heating and cooling load estimation: heat balance (HB) and radiant time series (RTS).

1. COOLING LOAD CALCULATION PRINCIPLES

Cooling loads result from many conduction, convection, and radiation heat transfer processes through the building envelope and from internal sources and system components. Building components or contents that may affect cooling loads include the following:

- **External:** Walls, roofs, windows, skylights, doors, partitions, ceilings, and floors
- **Internal:** Lights, people, appliances, and equipment
- **Infiltration:** Air leakage and moisture migration
- **System:** Outdoor air, duct leakage and heat gain, reheat, fan and pump energy, and energy recovery

1.1 TERMINOLOGY

The variables affecting cooling load calculations are numerous, often difficult to define precisely, and always intricately interrelated. Many cooling load components vary widely in magnitude, and possibly direction, during a 24 h period. Because these cyclic changes in load components often are not in phase with each other, each component must be analyzed to establish the maximum cooling load for a building or zone. A **zoned system** (i.e., one serving several independent areas, each with its own temperature control) needs to provide no greater total cooling load capacity than the largest hourly sum of simultaneous zone loads throughout a design day; however, it must handle the peak cooling load for each zone at its individual peak hour. At some times of day during heating or intermediate seasons, some zones may require heating while others require cooling. The zones' ventilation, humidification, or dehumidification needs must also be considered.

Heat Flow Rates

In air-conditioning design, the following four related heat flow rates, each of which varies with time, must be differentiated.

Space Heat Gain. This instantaneous rate of heat gain is the rate at which heat enters into and/or is generated within a space. Heat gain is classified by its mode of entry into the space and whether it is sensible or latent. **Entry modes** include (1) solar radiation through transparent surfaces; (2) heat conduction through exterior walls and roofs; (3) heat conduction through ceilings, floors, and interior partitions; (4) heat generated in the space by occupants, lights, and appliances; (5) energy transfer through direct-with-space ventilation and infiltration of outdoor air; and (6) miscellaneous heat gains. **Sensible heat** is added directly to the conditioned space by conduction, convection, and/or radiation. **Latent heat** gain occurs when moisture is added to the space (e.g., from vapor emitted by occupants and equipment). To maintain a constant humidity ratio, water vapor must condense on the cooling apparatus and be removed at the same rate it is added to the space. The amount of energy required to offset latent heat gain essentially equals the product of the condensation rate and latent heat of condensation. In selecting cooling equipment, distinguish between sensible and latent heat gain: every cooling apparatus has different maximum removal capacities for sensible versus latent heat for particular operating conditions. In extremely dry climates, humidification may be required, rather than dehumidification, to maintain thermal comfort.

Radiant Heat Gain. Radiant energy must first be absorbed by surfaces that enclose the space (walls, floor, and ceiling) and objects in the space (furniture, etc.). When these surfaces and objects become warmer than the surrounding air, some of their heat transfers to the air by convection. The composite heat storage capacity of these surfaces and objects determines the rate at which their respective surface temperatures increase for a given radiant input, and thus governs the relationship between the radiant portion of heat gain and its corresponding part of the space cooling load (Figure 1). The thermal storage effect is critical in differentiating between instantaneous heat gain for a given space and its cooling load at that moment. Predicting

The preparation of this chapter is assigned to TC 4.1, Load Calculation Data and Procedures.

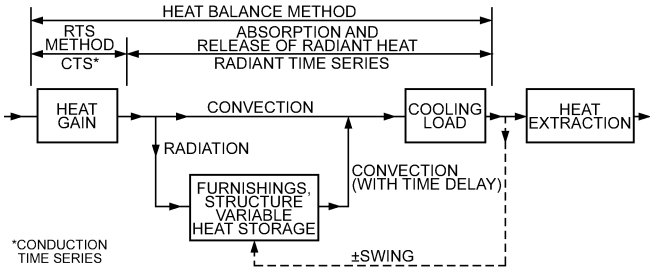

Fig. 1 Origin of Difference Between Magnitude of Instantaneous Heat Gain and Instantaneous Cooling Load

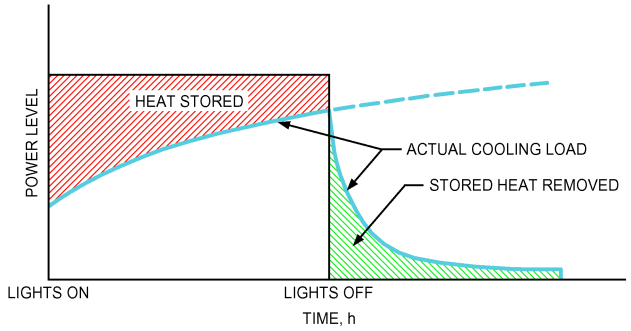

Fig. 2 Thermal Storage Effect in Cooling Load from Lights

the nature and magnitude of this phenomenon to estimate a realistic cooling load for a particular set of circumstances has long been of interest to design engineers; the Bibliography lists some early work on the subject.

Space Cooling Load. This is the rate at which sensible and latent heat must be removed from the space to maintain a constant space air temperature and humidity. The sum of all space instantaneous heat gains at any given time does not necessarily (or even frequently) equal the cooling load for the space at that same time.

Space Heat Extraction Rate. The rates at which sensible and latent heat are removed from the conditioned space equal the space cooling load only if the room air temperature and humidity are constant. Along with the intermittent operation of cooling equipment, control systems usually allow a minor cyclic variation or swing in room temperature; humidity is often allowed to float, but it can be controlled. Therefore, proper simulation of the control system gives a more realistic value of energy removal over a fixed period than using values of the space cooling load. However, this is primarily important for estimating energy use over time; it is not needed to calculate design peak cooling load for equipment selection.

Cooling Coil Load. The rate at which energy is removed at a cooling coil serving one or more conditioned spaces equals the sum of instantaneous space cooling loads (or space heat extraction rate, if it is assumed that space temperature and humidity vary) for all spaces served by the coil, plus any system loads. System loads include fan heat gain, duct heat gain, and outdoor air heat and moisture brought into the cooling equipment to satisfy the ventilation air requirement.

Time Delay Effect

Energy absorbed by walls, floor, furniture, etc., contributes to space cooling load only after a time lag. Some of this energy is still present and reradiating even after the heat sources have been switched off or removed, as shown in Figure 2.

There is always significant delay between the time a heat source is activated, and the point when reradiated energy equals that being instantaneously stored. This time lag must be considered when calculating cooling load, because the load required for the space can be much lower than the instantaneous heat gain being generated, and the space's peak load may be significantly affected.

Accounting for the time delay effect is the major challenge in cooling load calculations. Several methods, including the two presented in this chapter, have been developed to take the time delay effect into consideration.

1.2 COOLING LOAD CALCULATION METHODS

This chapter presents two load calculation methods that vary significantly from previous methods. The technology involved, however (the principle of calculating a heat balance for a given space) is not new. The first of the two methods is the **heat balance (HB) method**; the second is **radiant time series (RTS)**, which is a simplification of the HB procedure. Both methods are explained in their respective sections.

Cooling load calculation of an actual, multiple-room building requires a complex computer program implementing the principles of either method.

Cooling Load Calculations in Practice

Load calculations should accurately describe the building. All load calculation inputs should be as accurate as reasonable, without using safety factors. Introducing compounding safety factors at multiple levels in the load calculation results in an unrealistic and oversized load.

Variation in heat transmission coefficients of typical building materials and composite assemblies, differing motivations and skills of those who construct the building, unknown infiltration rates, and the manner in which the building is actually operated are some of the variables that make precise calculation impossible. Even if the designer uses reasonable procedures to account for these factors, the calculation can never be more than a good estimate of the actual load. Frequently, a cooling load must be calculated before every parameter in the conditioned space can be properly or completely defined. An example is a cooling load estimate for a new building with many floors of unleased spaces for which detailed partition requirements, furnishings, lighting, and layout cannot be predefined. Potential tenant modifications once the building is occupied also must be considered. Load estimating requires proper engineering judgment that includes a thorough understanding of heat balance fundamentals.

Perimeter spaces exposed to high solar heat gain often need cooling during sunlit portions of traditional heating months, as do completely interior spaces with significant internal heat gain. These spaces can also have significant heating loads during nonsunlit hours or after periods of nonoccupancy, when adjacent spaces have cooled below interior design temperatures. The heating loads involved can be estimated conventionally to offset or to compensate for them and prevent overheating, but they have no direct relationship to the spaces' design heating loads.

Correct design and sizing of air-conditioning systems require more than calculation of the cooling load in the space to be conditioned. The type of air-conditioning system, ventilation rate, reheat, fan energy, fan location, duct heat loss and gain, duct leakage, heat extraction lighting systems, type of return air system, and any sensible or latent heat recovery all affect system load and component sizing. Adequate system design and component sizing require that system performance be analyzed as a series of psychrometric processes.

System design could be driven by either sensible or latent load, and both need to be checked. In a sensible-load-driven space (the most common case), the cooling supply air has surplus capacity to dehumidify, but this is usually permissible. For a space driven by latent

Licensed for single user. © 2021, ASHRAE, Inc.

load (e.g., an auditorium), supply airflow based on sensible load is likely not to have enough dehumidifying capability, so subcooling and reheating or some other dehumidification process is needed.

This chapter is primarily concerned with a given space or zone in a building. When estimating loads for a group of spaces (e.g., for an air-handling system that serves multiple zones), the assembled zones must be analyzed to consider (1) the simultaneous effects taking place; (2) any diversification of heat gains for occupants, lighting, or other internal load sources; (3) ventilation; and/or (4) any other unique circumstances. With large buildings that involve more than a single HVAC system, simultaneous loads and any additional diversity also must be considered when designing the central equipment that serves the systems. Methods presented in this chapter are expressed as hourly load summaries, reflecting 24 h input schedules and profiles of the individual load variables. Specific systems and applications may require different profiles.

1.3 DATA ASSEMBLY

Calculating space cooling loads requires detailed building design information and weather data at design conditions. Generally, the following information should be compiled.

Building Characteristics. Building materials, component size, external surface colors, and shape are usually determined from building plans and specifications.

Configuration. Determine building location, orientation, and external shading from building plans and specifications. Shading from adjacent buildings can be determined from a site plan or by visiting the proposed site, but its probable permanence should be carefully evaluated before it is included in the calculation. The possibility of abnormally high ground-reflected solar radiation (e.g., from adjacent water, sand, or parking lots) or solar load from adjacent reflective buildings should not be overlooked.

Outdoor Design Conditions. Obtain appropriate weather data, and select outdoor design conditions. Chapter 14 provides information for many weather stations; note, however, that these design dry-bulb and mean coincident wet-bulb temperatures may vary considerably from data traditionally used in various areas. Use judgment to ensure that results are consistent with expectations. Also, consider prevailing wind velocity and the relationship of a project site to the selected weather station.

Recent research projects have greatly expanded the amount of available weather data (e.g., ASHRAE 2012). In addition to the conventional dry bulb with mean coincident wet bulb, data are now available for wet bulb and dew point with mean coincident dry bulb. Peak space load generally coincides with peak solar or peak dry bulb, but peak system load often occurs at peak wet-bulb temperature. The relationship between space and system loads is discussed further in following sections of the chapter.

To estimate conductive heat gain through exterior surfaces and infiltration and outdoor air loads at any time, applicable outdoor dry- and wet-bulb temperatures must be used. Chapter 14 gives monthly cooling load design values of outdoor conditions for many locations. These are generally midafternoon conditions; for other times of day, the daily range profile method described in Chapter 14 can be used to estimate dry- and wet-bulb temperatures. Peak cooling load is often determined by solar heat gain through fenestration; this peak may occur in winter months and/or at a time of day when outdoor air temperature is not at its maximum.

Indoor Design Conditions. Select indoor dry-bulb temperature, indoor relative humidity, and ventilation rate. Include permissible variations and control limits. Consult ASHRAE *Standard* 90.1 for energy-savings conditions, and *Standard* 55 for ranges of indoor conditions needed for thermal comfort.

Internal Heat Gains and Operating Schedules. Obtain planned density and a proposed schedule of lighting, occupancy, internal equipment, appliances, and processes that contribute to the internal thermal load.

Areas. Use consistent methods for calculation of building areas. For fenestration, the definition of a component's area must be consistent with associated ratings.

Gross surface area. It is efficient and conservative to derive gross surface areas from outer building dimensions, ignoring wall and floor thicknesses and avoiding separate accounting of floor edge and wall corner conditions. Measure floor areas to the outside of adjacent exterior walls or to the centerline of adjacent partitions. When apportioning to rooms, façade area should be divided at partition centerlines. Wall height should be taken as floor-to-floor height.

The outer-dimension procedure is expedient for load calculations, but it is not consistent with rigorous definitions used in building-related standards. The resulting differences do not introduce significant errors in this chapter's procedures.

Fenestration area. As discussed in Chapter 15, fenestration ratings [U-factor and solar heat gain coefficient (SHGC)] are based on the entire product area, including frames. Thus, for load calculations, fenestration area is the area of the rough opening in the wall or roof.

Net surface area. Net surface area is the gross surface area less any enclosed fenestration area.

2. INTERNAL HEAT GAINS

Internal heat gains from people, lights, motors, appliances, and equipment can contribute the majority of the cooling load in a modern building. As building envelopes have improved in response to more restrictive energy codes, internal loads have increased because of factors such as increased use of computers and the advent of dense-occupancy spaces (e.g., call centers). Internal heat gain calculation techniques are identical for both heat balance (HB) and radiant time series (RTS) cooling-load calculation methods, so internal heat gain data are presented here independent of calculation methods.

2.1 PEOPLE

Table 1 gives representative rates at which sensible heat and moisture are emitted by humans in different states of activity. In high-density spaces, such as auditoriums, these sensible and latent heat gains comprise a large fraction of the total load. Even for short-term occupancy, the extra sensible heat and moisture introduced by people may be significant. See Chapter 9 for detailed information; however, Table 1 summarizes design data for common conditions.

The conversion of sensible heat gain from people to space cooling load is affected by the thermal storage characteristics of that space because some percentage of the sensible load is radiant energy. Latent heat gains are usually considered instantaneous, but research is yielding practical models and data for the latent heat storage of and release from common building materials.

2.2 LIGHTING

Because lighting is often a major space cooling load component, an accurate estimate of the space heat gain it imposes is needed. Calculation of this load component is not straightforward; the rate of cooling load from lighting at any given moment can be quite different from the heat equivalent of power supplied instantaneously to those lights, because of heat storage.

Instantaneous Heat Gain from Lighting

The primary source of heat from lighting comes from light-emitting elements, or lamps, although significant additional heat may be generated from ballasts and other appurtenances in the

Athletics	Gymnasium	585	525	210	315		

Notes:
1. Tabulated values are based on 24°C room dry-bulb temperature. For 27°C room dry bulb, total heat remains the same, but sensible heat values should be decreased by approximately 20%, and latent heat values increased accordingly.
2. Also see Table 4, Chapter 9, for additional rates of metabolic heat generation.
3. All values are rounded to nearest 5 W.

[a] Adjusted heat gain is based on normal percentage of men, women, and children for the application listed, and assumes that gain from an adult female is 85% of that for an adult male, and gain from a child is 75% of that for an adult male.
[b] Values approximated from data in Table 6, Chapter 9, where *V* is air velocity with limits shown in that table.
[c] Adjusted heat gain includes 18 W for food per individual (9 W sensible and 9 W latent).
[d] Figure one person per alley actually bowling, and all others as sitting (117 W) or standing or walking slowly (231 W).

Licensed for single user. © 2021, ASHRAE, Inc.

luminaires. Generally, the instantaneous rate of sensible heat gain from electric lighting may be calculated from

$$q_{el} = WF_{ul}F_{sa} \quad (1)$$

where

q_{el} = heat gain, W
W = total light wattage, W
F_{ul} = lighting use factor
F_{sa} = lighting special allowance factor

The **total light wattage** is obtained from the ratings of all lamps installed, both for general illumination and for display use. Ballasts are not included, but are addressed by a separate factor. Wattages of magnetic ballasts are significant; the energy consumption of high-efficiency electronic ballasts might be insignificant compared to that of the lamps.

The **lighting use factor** is the ratio of wattage in use, for the conditions under which the load estimate is being made, to total installed wattage. For commercial applications such as stores, the use factor is generally 1.0.

The **special allowance factor** is the ratio of the lighting fixtures' power consumption, including lamps and ballast, to the nominal power consumption of the lamps. For incandescent lights, this factor is 1. For fluorescent lights, it accounts for power consumed by the ballast as well as the ballast's effect on lamp power consumption. The special allowance factor can be less than 1 for electronic ballasts that lower electricity consumption below the lamp's rated power consumption. Use manufacturers' values for system (lamps + ballast) power, when available.

For high-intensity-discharge lamps (e.g. metal halide, mercury vapor, high- and low-pressure sodium vapor lamps), the actual lighting system power consumption should be available from the manufacturer of the fixture or ballast. Ballasts available for metal halide and high-pressure sodium vapor lamps may have special allowance factors from about 1.3 (for low-wattage lamps) down to 1.1 (for high-wattage lamps).

An alternative procedure is to estimate the lighting heat gain on a per-square-metre basis. Such an approach may be required when final lighting plans are not available. Table 2 shows the maximum lighting power density (LPD) (lighting heat gain per square metre) allowed by ASHRAE *Standard* 90.1-2013 for a range of space types.

In addition to determining the lighting heat gain, the fraction of lighting heat gain that enters the conditioned space may need to be distinguished from the fraction that enters an unconditioned space; of the former category, the distribution between radiative and convective heat gain must be established.

Fisher and Chantrasrisalai (2006) and Zhou et al. (2016) experimentally studied 12 luminaire types and recommended several categories of luminaires, as shown in Table 3. The table provides a range of design data for the conditioned space fraction, short-wave radiative fraction, and long-wave radiative fraction under typical operating conditions: airflow rate of 5 L/(s·m^2), supply air temperature between 15 and 16.7°C, and room air temperature between 22 and 24°C. The recommended fractions in Table 3 are based on lighting heat input rates range of 9.7 to 28 W/m^2. For higher design power input, the lower bounds of the space and short-wave fractions should be used; for design power input below this range, the upper bounds of the space and short-wave fractions should be used. The **space fraction** in the table is the fraction of lighting heat gain that goes to the room; the fraction going to the plenum can be computed as 1 – the space fraction. The **radiative fraction** is the radiative part of the lighting heat gain that goes to the room. The convective fraction of the lighting heat gain that goes to the room is 1 – the radiative fraction. Using values in the middle of the range yields sufficiently accurate results. However, values that better suit a specific situation may be determined according to the notes for Table 3.

Table 3's data apply to both ducted and nonducted returns. However, application of the data, particularly the ceiling plenum fraction, may vary for different return configurations. For instance, for a room with a ducted return, although a portion of the lighting energy initially dissipated to the ceiling plenum is quantitatively equal to the plenum fraction, a large portion of this energy would likely end up as the conditioned space cooling load and a small portion would end up as the cooling load to the return air.

If the space airflow rate is different from the typical condition [i.e., about 5 L/(s·m^2)], Figure 3 can be used to estimate the lighting heat gain parameters. Design data shown in Figure 3 are only applicable for the recessed fluorescent luminaire without lens.

Although design data presented in Table 3 and Figure 3 can be used for a vented luminaire with side-slot returns, they are likely not applicable for a vented luminaire with lamp compartment returns, because in the latter case, all heat convected in the vented luminaire

[e]Sometimes called a picking area.

[f]An additional 5.7 W/m² is allowed *only* if this additional lighting is controlled separately from the base allowance of 4.5 W/m².

is likely to go directly to the ceiling plenum, resulting in zero convective fraction and a much lower space fraction. Therefore, the design data should only be used for a configuration where conditioned air is returned through the ceiling grille or luminaire side slots.

For other luminaire types, it may be necessary to estimate the heat gain for each component as a fraction of the total lighting heat gain by using judgment to estimate heat-to-space and heat-to-return percentages.

Table 3 Lighting Heat Gain Parameters for Typical Operating Conditions

Luminaire Category	Space Fraction	Radiative Fraction	Notes
Recessed fluorescent luminaire without lens	0.64 to 0.74	0.48 to 0.68	• Use middle values in most situations • May use higher space fraction, and lower radiative fraction for luminaire with side-slot returns • May use lower values of both fractions for direct/indirect luminaire • May use higher values of both fractions for ducted returns
Recessed fluorescent luminaire with lens	0.40 to 0.50	0.61 to 0.73	• May adjust values in the same way as for recessed fluorescent luminaire without lens
Downlight compact fluorescent luminaire	0.12 to 0.24	0.95 to 1.0	• Use middle or high values if detailed features are unknown • Use low value for space fraction and high value for radiative fraction if there are large holes in luminaire's reflector
Downlight incandescent luminaire	0.70 to 0.80	0.95 to 1.0	• Use middle values if lamp type is unknown • Use low value for space fraction if standard lamp (i.e. A-lamp) is used • Use high value for space fraction if reflector lamp (i.e. BR-lamp) is used
Non-in-ceiling fluorescent luminaire	1.0	0.5 to 0.57	• Use lower value for radiative fraction for surface-mounted luminaire • Use higher value for radiative fraction for pendant luminaire
Recessed LED troffer partial aperture diffuser	0.49 to 0.64	0.37 to 0.47	• Use middle value in most cases. • May use higher space fraction for ducted return configuration and lower space fraction for high supply air temperature. • May use higher radiant value for ducted return configuration and lower value for large supply airflow rate.
Recessed LED troffer uniform diffuser	0.44 to 0.66	0.32 to 0.41	• Use middle value in most cases. • May use higher space fraction for smaller supply airflow rate and lower value for larger supply airflow rate. • May use higher radiant value for ducted return configuration and lower value for larger supply airflow rate.
Recessed high-efficacy LED troffer	0.59	0.51	
Recessed LED downlight	0.40 to 0.56	0.15 to 0.18	• Use middle value in most cases. • May use higher space fraction value for high supply air temperature and lower value for smaller air flowrate. • May use higher radiant value for dimming control and lower value for large supply air flowrate.
Recessed LED retrofit kit 2×4	0.41 to 0.53	0.31 to 0.42	• Use middle value in most cases. • May use higher space fraction value for large supply air flowrate and lower value for ducted return configuration. • May use higher radiant value for ducted return configuration and lower value for larger supply airflow rate.
Recessed LED color tuning fixture	0.53 to 0.56	0.40 to 0.42	Use middle value in most cases.
High-bay LED fixture	1.0	0.42 to 0.51	Use middle value in most cases.
Linear pendant LED fixture	1.0	0.55 to 0.60	Use middle value in most cases.

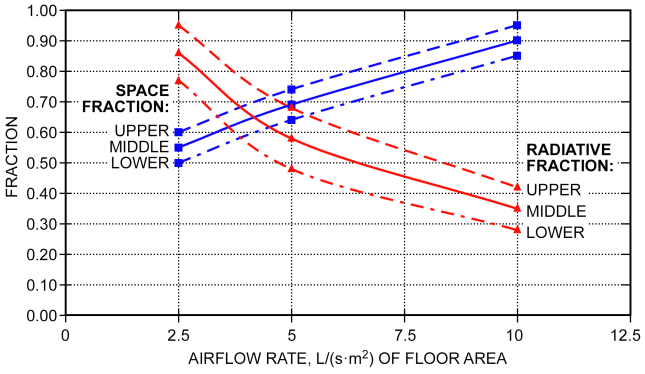

Fig. 3 Lighting Heat Gain Parameters for Recessed Fluorescent Luminaire Without Lens
(Fisher and Chantrasrisalai 2006)

Because of the directional nature of downlight luminaires, a large portion of the short-wave radiation typically falls on the floor. When converting heat gains to cooling loads in the RTS method, the solar **radiant time factors (RTFs)** may be more appropriate than nonsolar RTFs. (Solar RTFs are calculated assuming most solar radiation is intercepted by the floor; nonsolar RTFs assume uniform distribution by area over all interior surfaces.) This effect may be significant for rooms where lighting heat gain is high and for which solar RTFs are significantly different from nonsolar RTFs.

2.3 ELECTRIC MOTORS

Instantaneous sensible heat gain from equipment operated by electric motors in a conditioned space is calculated as

$$q_{em} = (P/E_M)F_{UM}F_{LM} \quad (2)$$

where

q_{em} = heat equivalent of equipment operation, W
P = motor power rating, W
E_M = motor efficiency, decimal fraction <1.0
F_{UM} = motor use factor, 1.0 or decimal fraction <1.0
F_{LM} = motor load factor, 1.0 or decimal fraction <1.0

The motor use factor may be applied when motor use is known to be intermittent, with significant nonuse during all hours of operation

(e.g., overhead door operator). For conventional applications, its value is 1.0.

The motor load factor is the fraction of the rated load delivered under the conditions of the cooling load estimate. Equation (2) assumes that both the motor and driven equipment are in the conditioned space. If the motor is outside the space or airstream,

$$q_{em} = PF_{UM}F_{LM} \tag{3}$$

When the motor is inside the conditioned space or airstream but the driven machine is outside,

$$q_{em} = P\left(\frac{1.0 - E_M}{E_M}\right)F_{UM}F_{LM} \tag{4}$$

Equation (4) also applies to a fan or pump in the conditioned space that exhausts air or pumps fluid outside that space.

Table 4A and 4B gives minimum efficiencies and related data representative of typical electric motors from ASHRAE *Standard* 90.1-2013. If electric motor load is an appreciable portion of cooling load, the motor efficiency should be obtained from the manufacturer. Also, depending on design, maximum efficiency might occur anywhere between 75 to 110% of full load; if under- or overloaded, efficiency could vary from the manufacturer's listing.

Overloading or Underloading

Heat output of a motor is generally proportional to motor load, within rated overload limits. Because of typically high no-load motor current, fixed losses, and other reasons, F_{LM} is generally assumed to be unity, and no adjustment should be made for underloading or overloading unless the situation is fixed and can be accurately established, and reduced-load efficiency data can be obtained from the motor manufacturer.

Radiation and Convection

Unless the manufacturer's technical literature indicates otherwise, motor heat gain normally should be equally divided between radiant and convective components for the subsequent cooling load calculations.

2.4 APPLIANCES

A cooling load estimate should take into account heat gain from all appliances (electrical, gas, or steam). Because of the variety of appliances, applications, schedules, use, and installations, estimates can be very subjective. Often, the only information available about heat gain from equipment is that on its nameplate, which can overestimate actual heat gain for many types of appliances, as discussed in the section on Office Equipment.

Cooking Appliances

These appliances include common heat-producing cooking equipment found in conditioned commercial kitchens. Marn (1962) concluded that appliance surfaces contributed most of the heat to commercial kitchens and that when appliances were installed under an effective hood, the cooling load was independent of the fuel or energy used for similar equipment performing the same operations.

Gordon et al. (1994) and Smith et al. (1995) found that gas appliances may exhibit slightly higher heat gains than their electric counterparts under wall-canopy hoods operated at typical ventilation rates. This is because heat contained in combustion products exhausted from a gas appliance may increase the temperatures of the appliance and surrounding surfaces, as well as the hood above the appliance, more so than the heat produced by its electric counterpart. These higher-temperature surfaces radiate heat to the kitchen, adding moderately to the radiant gain directly associated with the appliance cooking surface.

Marn (1962) confirmed that, where appliances are installed under an effective hood, only radiant gain adds to the cooling load; convective and latent heat from cooking and combustion products are exhausted and do not enter the kitchen. Gordon et al. (1994) and Smith et al. (1995) substantiated these findings. Chapter 33 of the 2019 *ASHRAE Handbook—HVAC Applications* has more information on kitchen ventilation.

Sensible Heat Gain for Hooded Cooking Appliances. To establish a heat gain value, nameplate energy input ratings may be used with appropriate usage and radiation factors. Where specific rating data are not available (nameplate missing, equipment not yet purchased, etc.), representative heat gains listed in Tables 5A to 5E (Swierczyna et al. 2008, 2009) for a wide variety of commonly

Licensed for single user. © 2021, ASHRAE, Inc.

encountered equipment items. In estimating appliance load, probabilities of simultaneous use and operation for different appliances located in the same space must be considered.

Radiant heat gain from hooded cooking equipment can range from 15 to 45% of the actual appliance energy consumption (Gordon et al. 1994; Smith et al. 1995; Swierczyna et al. 2008; Talbert et al. 1973). This ratio of heat gain to appliance energy consumption may be expressed as a radiation factor, and it is a function of both appliance type and fuel source. The radiation factor F_R is applied to the average rate of appliance energy consumption, determined by applying usage factor F_U to the nameplate or rated energy input. Marn (1962) found that radiant heat temperature rise can be substantially reduced by shielding the fronts of cooking appliances. Although this approach may not always be practical in a commercial kitchen, radiant gains can also be reduced by adding side panels or partial enclosures that are integrated with the exhaust hood.

Heat Gain from Meals. For each meal served, approximately 15 W of heat, of which 75% is sensible and 25% is latent, is transferred to the dining space.

Heat Gain for Generic Appliances. The average rate of appliance energy consumption can be estimated from the nameplate or rated energy input q_{input} by applying a duty cycle or usage factor F_U. Thus, sensible heat gain q_s for generic electric, steam, and gas appliances installed under a hood can be estimated using one of the following equations:

$$q_s = q_{input} F_U F_R \quad (5)$$

or

$$q_s = q_{input} F_L \quad (6)$$

where F_L is the ratio of sensible heat gain to the manufacturer's rated energy input. However, ASHRAE research (Swierczyna et al. 2008, 2009) showed the design value for heat gain from a hooded appliance at idle (ready-to-cook) conditions based on its energy consumption rate is, at best, a rough estimate. When appliance heat gain measurements during idle conditions were regressed against energy consumption rates for gas and electric appliances, the appliances' emissivity, insulation, and surface cooling (e.g., through ventilation rates) scattered the data points widely, with large devia-

tions from the average values. Because large errors could occur in the heat load calculation for specific appliance lines by using a general radiation factor, heat gain values in Table 5 should be applied in the HVAC design.

Table 5 lists usage factors, radiation factors, and load factors based on appliance energy consumption rate for typical electrical, steam, and gas appliances under standby (idle or ready-to-cook) and cooking conditions, hooded and unhooded.

Warewashing Applications. Typically, hot-water sanitizing and conveyor-type dish machines have either a dishwasher/condensing hood or direct-connected ductwork. If the ventilation is not operating properly, there are significant sensible and latent gains to the space. Chemical sanitizing and vapor reduction models are typically unhooded; consequently, the dish machines produce internal gains that must be accounted for and managed by the building HVAC system.

Sensible radiant and convective gains are affected by dishwasher insulation, and latent convective gains are affected by door seals. Heat loads may vary.

Recirculating Systems. Cooking appliances ventilated by recirculating systems or "ductless" hoods should be treated as unhooded appliances when estimating heat gain. In other words, all energy consumed by the appliance and all moisture produced by cooking is introduced to the kitchen as a sensible or latent cooling load.

Recommended Heat Gain Values. Table 5 lists recommended rates of heat gain from typical commercial cooking appliances. Data in the "hooded" columns assume installation under a properly designed exhaust hood connected to a mechanical fan exhaust system operating at an exhaust rate for complete capture and containment of the thermal and effluent plume. Improperly operating hood systems load the space with a significant convective component of the heat gain.

Hospital and Laboratory Equipment

Hospital and laboratory equipment items are major sources of sensible and latent heat gains in conditioned spaces. Care is needed in evaluating the probability and duration of simultaneous usage when many components are concentrated in one area, such as a laboratory, an operating room, etc. Commonly, heat gain from equipment in a laboratory ranges from 50 to 220 W/m^2 or, in laboratories with outdoor exposure, as much as four times the heat gain from all other sources combined.

Medical Equipment. It is more difficult to provide generalized heat gain recommendations for medical equipment than for general office equipment because medical equipment is much more varied in type and in application. Some heat gain testing has been done, but the equipment included represents only a small sample of the type of equipment that may be encountered.

Data presented for medical equipment in Table 6 are relevant for portable and bench-top equipment. Medical equipment is very specific and can vary greatly from application to application. The data are presented to provide guidance in only the most general sense. For large equipment, such as MRI, heat gain must be obtained from the manufacturer.

Laboratory Equipment. Equipment in laboratories is similar to medical equipment in that it varies significantly from space to space. Chapter 16 of the 2019 *ASHRAE Handbook—HVAC Applications* discusses heat gain from equipment, which may range from 50 to 270 W/m^2 in highly automated laboratories. Table 7 lists some values for laboratory equipment, but, as with medical equipment, it is for general guidance only. Wilkins and Cook (1999) also examined laboratory equipment heat gains.

Office Equipment

Computers, printers, copiers, etc., can generate very significant heat gains, sometimes greater than all other gains combined. ASHRAE research project RP-822 developed a method to measure the actual heat gain from equipment in buildings and the radiant/convective percentages (Hosni et al. 1998; Jones et al. 1998). This methodology was then incorporated into ASHRAE research project RP-1055 and applied to a wide range of equipment (Hosni et al. 1999) as a follow-up to independent research by Wilkins and McGaffin (1994) and Wilkins et al. (1991). Komor (1997) found similar results. Analysis of measured data showed that results for office equipment could be generalized, but results from laboratory and hospital equipment proved too diverse. The following general guidelines for office equipment are a result of these studies.

Nameplate Versus Measured Energy Use. Nameplate data rarely reflect the actual power consumption of office equipment. Actual power consumption is assumed to equal total (radiant plus convective) heat gain, but its ratio to the nameplate value varies widely. ASHRAE research project RP-1055 (Hosni et al. 1999) found that, for general office equipment with nameplate power consumption of less than 1000 W, the actual ratio of total heat gain to nameplate ranged from 25 to 50%, but when all tested equipment is considered, the range is broader. Generally, if the nameplate value is the only information known and no actual heat gain data are available for similar equipment, it is conservative to use 50% of nameplate as heat gain and more nearly correct if 25% of nameplate is used. Much better results can be obtained, however, by considering heat gain to be predictable based on the type of equipment. However, if the device has a mainly resistive internal electric load (e.g., a space heater), the nameplate rating may be a good estimate of its peak energy dissipation.

[b]For equipment peak heat gain value, highest 15-min interval of recorded data is listed in tables.

Computers. Based on tests by Hosni et al. (1999) and Wilkins and McGaffin (1994), nameplate values on computers should be ignored when performing cooling load calculations. Tables 8A, 8B, and 8C (Bach and Sarfraz 2017) present typical heat gain values for computers of varying types and models.

Monitors. Table 8D shows typical values for various sizes and types.

Flat-panel monitors have replaced CRT monitors in almost all workplaces. Power consumption, and thus heat gain, for flat-panel displays are significantly lower than for CRTs.

Laser Printers. Hosni et al. (1999) found that power consumption, and therefore the heat gain, of laser printers depended largely on the level of throughput for which the printer was designed. Smaller printers tend to be used more intermittently, and larger printers may run continuously for longer periods.

Table 9 presents data on typical printers. These data can be applied by taking the value for continuous operation and then applying an appropriate diversity factor. This would likely be most appropriate for larger open office areas. Another approach, which may be appropriate for a single room or small area, is to take the value that most closely matches the expected operation of the printer with no diversity.

Copiers. Bach and Sarfraz (2017) also tested photocopy machines, including desktop and office (freestanding high-volume copiers) models. Larger machines used in production environments were not addressed. Table 9 summarizes the results. Desktop copiers rarely operate continuously, but office copiers frequently operate continuously for periods of an hour or more. Large, high-volume photocopiers often include provisions for exhausting air outdoors; if so equipped, the direct-to-space or system makeup air heat gain needs to be included in the load calculation. Also, when the air is dry, humidifiers are often operated near copiers to limit static electricity; if this occurs during cooling mode, their load on HVAC systems should be considered.

Miscellaneous Office Equipment. Table 10 presents data on miscellaneous office equipment such as vending machines and other equipment tested by Bach and Sarfraz (2017).

Diversity. The ratio of measured peak electrical load at equipment panels to the sum of the maximum electrical load of each individual item of equipment is the usage diversity. A small, one- or two-person office containing equipment listed in Tables 8 to 10 usually

contributes heat gain to the space at the sum of the appropriate listed values. Progressively larger areas with many equipment items always experience some degree of usage diversity resulting from whatever percentage of such equipment is not in operation at any given time.

Wilkins and McGaffin (1994) measured diversity in 23 areas within five different buildings totaling over 25 600 m^2. Diversity was found to range between 37 and 78%, with the average (normalized based on area) being 46%. Figure 4 shows the relationship between nameplate, sum of peaks, and actual electrical load with diversity accounted for, based on the average of the total area tested. Data on actual diversity can be used as a guide, but diversity varies significantly with occupancy. The proper diversity factor for an office of call center operators is different from that for an office of sales representatives who travel regularly.

ASHRAE research project RP-1093 derived diversity profiles for use in energy calculations (Abushakra et al. 2004; Claridge et al. 2004). Those profiles were derived from available measured data sets for a variety of office buildings, and indicated a range of peak weekday diversity factors for lighting ranging from 70 to 85% and for receptacles (appliance load) between 42 and 89%.

Heat Gain per Unit Area. Bach and Sarfraz (2017), Wilkins and Hosni (2000, 2011) and Wilkins and McGaffin (1994) summarized research on a heat gain per unit area basis. Diversity testing showed that the actual heat gain per unit area, or load factor, ranged from 4.7 to 11.6 W/m^2, with an average (normalized based on area) of 8.7 W/m^2. Spaces tested were fully occupied and highly automated, comprising 21 unique areas in five buildings, with a computer and monitor at every workstation. Table 11 presents a range of load factors with a subjective description of the type of space to which they would apply. The medium load density is likely to be appropriate for most standard office spaces. Medium/heavy or heavy load densities

3. INFILTRATION AND MOISTURE MIGRATION HEAT GAINS

Two other load components contribute to space cooling load directly without time delay from building mass: (1) infiltration, and (2) moisture migration through the building envelope.

3.1 INFILTRATION

Principles of estimating infiltration in buildings, with emphasis on the heating season, are discussed in Chapter 16. When economically feasible, somewhat more outdoor air may be introduced to a building than the total of that exhausted, to create a slight overall positive pressure in the building relative to the outdoors. Under these conditions, air usually exfiltrates, rather than infiltrates, through the building envelope and thus effectively eliminates infiltration sensible and latent heat gains. However, there is concern, especially in some climates, that water may condense within the building envelope; actively managing space air pressures to reduce this condensation problem, as well as infiltration, may be needed.

When positive air pressure is assumed, most designers do not include infiltration in cooling load calculations for commercial buildings. However, including some infiltration for spaces such entry areas or loading docks may be appropriate, especially when those spaces are on the windward side of buildings. But the downward stack effect, as occurs when indoor air is denser than the outdoor, might eliminate infiltration to these entries on lower floors of tall buildings; infiltration may occur on the upper floors during cooling conditions if makeup air is not sufficient.

Infiltration also depends on wind direction and magnitude, temperature differences, construction type and quality, and occupant use of exterior doors and operable windows. As such, it is impossible to accurately predict infiltration rates. Designers usually predict overall rates of infiltration using the number of **air changes per**

Table 11 Recommended Load Factors for Various Types of Offices

hour (ACH). A common guideline for climates and buildings typical of at least the central United States is to estimate the ACHs for winter heating conditions, and then use half that value for the cooling load calculations.

Standard Air Volumes

Because the specific volume of air varies appreciably, calculations are more accurate when made on the basis of air mass instead of volume. However, volumetric flow rates are often required for selecting coils, fans, ducts, etc.; basing volumes on measurement at standard conditions may be used for accurate results. One standard value is 1.2 kg_{da}/m^3 (0.833 m^3/kg). This density corresponds to about 16°C at saturation and 21°C dry air (at 101.325 kPa). Because air usually passes through the equipment at a density close to standard for locations below about 300 m, the accuracy desired normally requires no correction. When airflow is to be measured at a particular condition or point, such as at a coil entrance or exit, the corresponding specific volume can be read from the sea-level psychrometric chart. For higher elevations, the mass flow rates of air must be adjusted and higher-elevation psychrometric charts or algorithms must be used.

Heat Gain Calculations Using Standard Air Values

Air-conditioning design often requires the following information:

1. Total heat

Total heat gain q_t corresponding to the change of a given standard flow rate Q_s through an enthalpy difference Δh is

$$q_t = 1.2 Q_s \Delta h \quad (7)$$

where 1.2 = kg_{da}/m^3.

This total heat equation can also be expressed as

$$q_t = C_t Q_s \Delta h$$

where C_t = 1.2 is the air total heat factor, in $W/(m^3 \cdot s)$ per kJ/kg.

2. Sensible heat

Sensible heat gain q_s corresponding to the change of dry-bulb temperature Δt for given airflow (standard conditions) Q_s is

$$q_s = 1.2(1.006 + 1.84W) Q_s \Delta t \quad (8)$$

where

1.006 = specific heat of dry air, $kJ/(kg \cdot K)$
W = humidity ratio, kg_w/kg_{da}
1.84 = specific heat of water vapor, $kJ/(kg \cdot K)$

The specific heats are for a range from about –75 to 90°C. When $W = 0$, the value of $1.20(1.006 + 1.84W) = 1.21$; when $W = 0.01$, the value is 1.23; when $W = 0.02$, the value is 1.25; and when $W = 0.03$, the value is 1.27. Because a value of $W = 0.01$ approximates conditions found in many air-conditioning problems, the sensible heat change (in kW) has traditionally been found as

$$q_s = 1.23 Q_s \Delta t \quad (9)$$

This sensible heat equation can also be expressed as

$$q_s = C_s Q_s \Delta t$$

where C_s = 1.23 is the air sensible heat factor, in $W/(m^3 \cdot s \cdot K)$.

3. Latent heat

Latent heat gain q_l corresponding to the change of humidity ratio ΔW (in kg_w/kg_{da}) for given airflow (standard conditions) Q_s is

$$q_l = 1.20 \times 2500 Q_s \Delta W = 3010 Q_s \Delta W \quad (10)$$

where 2500 is the approximate heat content of 50% rh vapor at 24°C less the heat content of water at 10°C. A common design condition for the space is 50% rh at 24°C, and 10°C is normal condensate temperature from cooling and dehumidifying coils.

This latent heat equation can also be expressed as

$$q_l = C_l Q_s \Delta W$$

where C_l = 3010 is the air latent heat factor, in $W/(m^3 \cdot s)$.

4. Elevation correction for total, sensible, and latent heat equations

The constants 1.2, 1.23, and 3010 are useful in air-conditioning calculations at sea level (101.325 kPa) and for normal temperatures and moisture ratios. For other conditions, more precise values should be used. For an elevation of 1525 m (84.1 kPa), appropriate values are 1.00, 1.03, and 2500. Equations (8) to (10) can be corrected for elevations other than sea level by multiplying them by the ratio of pressure at sea level divided by the pressure at actual altitude. This can be derived from Equation (3) in Chapter 1 as

$$C_{x,alt} = C_{x,0} P / P_0$$

where $C_{x,0}$ is any sea-level C value and $P/P_0 = [1 - (\text{elevation} \times 2.25577 \times 10^{-5})]^{5.2559}$, where elevation is in metres.

Elevation Correction Examples

To correct the C values for El Paso, Texas, the elevation listed in the appendix of Chapter 14 is 1194 m. C values for Equations (7) to (10) can be corrected using Equation (3) in Chapter 1 as follows:

$$C_{t,1194} = 1.2 \times [1 - (1194 \times 2.25577 \times 10^{-5})]^{5.2559} = 1.04$$

$$C_{s,1194} = 1.23 \times [1 - (1194 \times 2.25577 \times 10^{-5})]^{5.2559} = 1.07$$

$$C_{l,1194} = 3010 \times [1 - (1194 \times 2.25577 \times 10^{-5})]^{5.2559} = 2608$$

To correct the C values for Albuquerque, New Mexico, the elevation listed in the appendix of Chapter 14 is 1619 m. C values for Equations (7) to (10) can be corrected as follows:

$$C_{t,1619} = 1.2 \times [1 - (1619 \times 2.25577 \times 10^{-5})]^{5.2559} = 0.99$$

$$C_{s,1619} = 1.23 \times [1 - (1619 \times 2.25577 \times 10^{-5})]^{5.2559} = 1.01$$

$$C_{l,1619} = 3010 \times [1 - (1619 \times 2.25577 \times 10^{-5})]^{5.2559} = 2475$$

3.2 LATENT HEAT GAIN FROM MOISTURE DIFFUSION

Diffusion of moisture through building materials is a natural phenomenon that is always present. Chapters 25 to 27 cover principles, materials, and specific methods used to control moisture. Moisture transfer through walls and roofs is often neglected in comfort air conditioning because the actual rate is quite small and the corresponding latent heat gain is insignificant. Permeability and permeance values for various building materials are given in Chapter 26. Vapor retarders should be specified and installed in the proper location to keep moisture transfer to a minimum, and to minimize condensation within the envelope. Moisture migration up through slabs-on-grade and basement floors has been found to be significant, but has historically not been addressed in cooling load calculations. Under-slab continuous moisture retarders and drainage can reduce upward moisture flow.

Some industrial applications require low moisture to be maintained in a conditioned space. In these cases, the latent heat gain accompanying moisture transfer through walls and roofs may be greater than any other latent heat gain. This gain is computed by

$$q_{l_m} = MA\Delta p_v (h_g - h_f) \quad (11)$$

where

q_{l_m} = latent heat gain from moisture transfer, W
M = permeance of wall or roof assembly, $ng/(s \cdot m^2 \cdot Pa)$
A = area of wall or roof surface, m^2

Licensed for single user. © 2021, ASHRAE, Inc.

Δp_v = vapor pressure difference, Pa
h_g = enthalpy at room conditions, kJ/kg
h_f = enthalpy of water condensed at cooling coil, kJ/kg
$h_g - h_f$ = 2500 kJ/kg when room temperature is 24°C and condensate off coil is 10°C

3.3 OTHER LATENT LOADS

Moisture sources within a building (e.g., shower areas, swimming pools or natatoriums, arboretums) can also contribute to latent load. Unlike sensible loads, which correlate to supply air quantities required in a space, latent loads usually only affect cooling coils sizing or refrigeration load. Because air from showers and some other moisture-generating areas is exhausted completely, those airborne latent loads do not reach the cooling coil and thus do not contribute to cooling load. However, system loads associated with ventilation air required to make up exhaust air must be recognized, and any recirculated air's moisture must be considered when sizing the dehumidification equipment.

For natatoriums, occupant comfort and humidity control are critical. In many instances, size, location, and environmental requirements make complete exhaust systems expensive and ineffective. Where recirculating mechanical cooling systems are used, evaporation (latent) loads are significant. Chapter 5 of the 2019 *ASHRAE Handbook—HVAC Applications* provides guidance on natatorium load calculations.

4. FENESTRATION HEAT GAIN

For spaces with neutral or positive air pressurization, the primary weather-related variable affecting cooling load is solar radiation. The effect of solar radiation is more pronounced and immediate on exposed, nonopaque surfaces. Chapter 14 includes procedures for calculating clear-sky solar radiation intensity and incidence angles for weather conditions encountered at specific locations. That chapter also includes some useful solar equations. Calculation of solar heat gain and conductive heat transfer through various glazing materials and associated mounting frames, with or without interior and/or exterior shading devices, is discussed in Chapter 15. This chapter covers application of such data to overall heat gain evaluation, and conversion of calculated heat gain into a composite cooling load for the conditioned space.

4.1 FENESTRATION DIRECT SOLAR, DIFFUSE SOLAR, AND CONDUCTIVE HEAT GAINS

For fenestration heat gain, use the following equations:

Direct beam solar heat gain q_b:

$$q_b = AE_{t,b}\,\mathrm{SHGC}(\theta)\mathrm{IAC}(\theta,\Omega) \tag{12}$$

Diffuse solar heat gain q_d:

$$q_d = A(E_{t,d} + E_{t,r})\langle \mathrm{SHGC}\rangle_D\,\mathrm{IAC}_D \tag{13}$$

Conductive heat gain q_c:

$$q_c = UA(T_{out} - T_{in}) \tag{14}$$

Total fenestration heat gain Q:

$$Q = q_b + q_d + q_c \tag{15}$$

where

A = window area, m^2
$E_{t,b}$, $E_{t,d}$, and $E_{t,r}$ = beam, sky diffuse, and ground-reflected diffuse irradiance, calculated using equations in Chapter 14
SHGC(θ) = beam solar heat gain coefficient as a function of incident angle θ; may be interpolated between values in Table 10 of Chapter 15
$\langle \mathrm{SHGC}\rangle_D$ = diffuse solar heat gain coefficient (also referred to as hemispherical SHGC); from Table 10 of Chapter 15
T_{in} = indoor temperature, °C
T_{out} = outdoor temperature, °C
U = overall U-factor, including frame and mounting orientation from Table 4 of Chapter 15, $W/(m^2 \cdot K)$
IAC(θ.Ω) = indoor solar attenuation coefficient for beam solar heat gain coefficient; = 1.0 if no indoor shading device. IAC(θ.Ω) is a function of shade type and, depending on type, may also be a function of beam solar angle of incidence θ and shade geometry
IAC_D = indoor solar attenuation coefficient for diffuse solar heat gain coefficient; = 1.0 if not indoor shading device. IAC_D is a function of shade type and, depending on type, may also be a function of shade geometry

If specific window manufacturer's SHGC and U-factor data are available, those should be used. For fenestration equipped with indoor shading (blinds, drapes, or shades), the indoor solar attenuation coefficients IAC(θ.Ω) and IAC_D are listed in Tables 14A to 14G of Chapter 15.

Note that, as discussed in Chapter 15, fenestration ratings (U-factor and SHGC) are based on the entire product area, including frames. Thus, for load calculations, fenestration area is the area of the entire opening in the wall or roof.

4.2 EXTERIOR SHADING

Nonuniform exterior shading, caused by roof overhangs, side fins, or building projections, requires separate hourly calculations for the externally shaded and unshaded areas of the window in question, with the indoor shading SHGC still used to account for any internal shading devices. The areas, shaded and unshaded, depend on the location of the shadow line on a surface in the plane of the glass. Sun (1968) developed fundamental algorithms for analysis of shade patterns. McQuiston and Spitler (1992) provide graphical data to facilitate shadow line calculation.

Equations for calculating shade angles [Chapter 15, Equations (34) to (37)] can be used to determine the shape and area of a moving shadow falling across a given window from external shading elements during the course of a design day. Thus, a subprofile of heat gain for that window can be created by separating its sunlit and shaded areas for each hour.

5. HEAT BALANCE METHOD

Cooling load estimation involves calculating a surface-by-surface conductive, convective, and radiative heat balance for each room surface and a convective heat balance for the room air. These principles form the foundation for all methods described in this chapter. The heat balance (HB) method solves the problem directly instead of introducing transformation-based procedures. The advantages are that it contains no arbitrarily set parameters, and no processes are hidden from view.

Some computations required by this rigorous approach require the use of computers. The heat balance procedure is not new. Many energy calculation programs have used it in some form for many years. The first implementation that incorporated all the elements to form a complete method was NBSLD (Kusuda 1967). The heat balance procedure is also implemented in both the BLAST and TARP energy analysis programs (Walton 1983). Before ASHRAE research project RP-875, the method had never been described completely or in a form applicable to cooling load calculations. The papers resulting from RP-875 describe the heat balance procedure in detail (Liesen and Pedersen 1997; McClellan and Pedersen 1997; Pedersen et al. 1997).

Licensed for single user. © 2021, ASHRAE, Inc.

The HB method is codified in the software called Hbfort that accompanies *Cooling and Heating Load Calculation Principles* (Pedersen et al. 1998).

ASHRAE research project RP-1117 constructed two model rooms for which cooling loads were physically measured using extensive instrumentation (Chantrasrisalai et al. 2003; Eldridge et al. 2003; Iu et al. 2003). HB calculations closely approximated measured cooling loads when provided with detailed data for the test rooms.

5.1 ASSUMPTIONS

All calculation procedures involve some kind of model; all models require simplifying assumptions and, therefore, are approximate. The most fundamental assumption is that air in the thermal zone can be modeled as **well mixed**, meaning its temperature is uniform throughout the zone. ASHRAE research project RP-664 (Fisher and Pedersen 1997) established that this assumption is valid over a wide range of conditions.

The next major assumption is that the surfaces of the room (walls, windows, floor, etc.) can be treated as having

- Uniform surface temperatures
- Uniform long-wave (LW) and short-wave (SW) irradiation
- Diffuse radiating surfaces
- One-dimensional heat conduction within

The resulting formulation is called the **heat balance (HB) model**. Note that the assumptions, although common, are quite restrictive and set certain limits on the information that can be obtained from the model.

5.2 ELEMENTS

Within the framework of the assumptions, the HB can be viewed as four distinct processes:

1. Outdoor-face heat balance
2. Wall conduction process
3. Indoor-face heat balance
4. Air heat balance

Figure 5 shows the relationship between these processes for a single opaque surface. The top part of the figure, inside the shaded box, is repeated for each surface enclosing the zone. The process for transparent surfaces is similar, but the absorbed solar component appears in the conduction process block instead of at the outdoor face, and the absorbed component splits into inward- and outward-flowing fractions. These components participate in the surface heat balances.

Outdoor-Face Heat Balance

The heat balance on the outdoor face of each surface is

$$q''_{\alpha sol} + q''_{LWR} + q''_{conv} - q''_{ko} = 0 \qquad (16)$$

where

$q''_{\alpha sol}$ = absorbed direct and diffuse solar radiation flux (q/A), W/m^2
q''_{LWR} = net long-wave radiation flux exchange with air and surroundings, W/m^2
q''_{conv} = convective exchange flux with outdoor air, W/m^2
q''_{ko} = conductive flux (q/A) into wall, W/m^2

All terms are positive for net flux to the face except q''_{ko}, which is traditionally taken to be positive from outdoors to inside the wall.

Each term in Equation (16) has been modeled in several ways, and in simplified methods the first three terms are combined by using the sol-air temperature.

Wall Conduction Process

The wall conduction process has been formulated in more ways than any of the other processes. Techniques include

- Numerical finite difference
- Numerical finite element
- Transform methods
- Time series methods

This process introduces part of the time dependence inherent in load calculation. Figure 6 shows surface temperatures on the indoor and outdoor faces of the wall element, and corresponding conductive heat fluxes away from the outer face and toward the indoor face. All four quantities are functions of time. Direct formulation of the

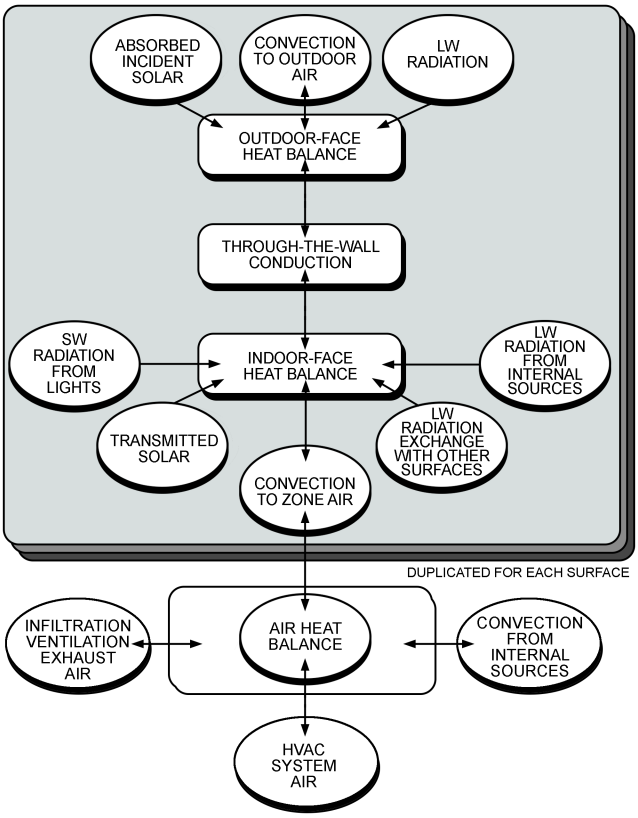

Fig. 5 Schematic of Heat Balance Processes in Zone

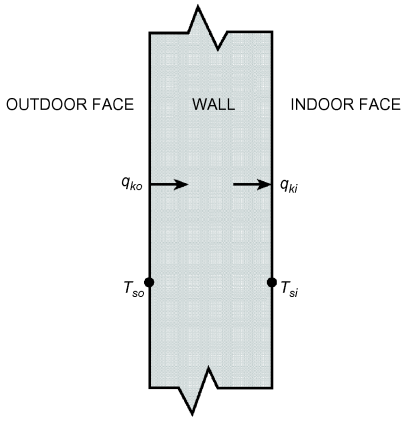

Fig. 6 Schematic of Wall Conduction Process

Licensed for single user. © 2021, ASHRAE, Inc.

process uses temperature functions as input or known quantities, and heat fluxes as outputs or resultant quantities.

In some models, surface heat transfer coefficients are included as part of the wall element, making the temperatures in question the indoor and outdoor air temperatures. This is not a desirable formulation, because it hides the heat transfer coefficients and prohibits changing them as airflow conditions change. It also prohibits treating the internal long-wave radiation exchange appropriately.

Because heat balances on both sides of the element induce both the temperature and heat flux, the solution must deal with this simultaneous condition. Two computational methods that have been used widely are finite difference and conduction transfer function methods. Because of the computational time advantage, the conduction transfer function formulation has been selected for presentation here.

Indoor-Face Heat Balance

The heart of the HB method is the internal heat balance involving the inner faces of the zone surfaces. This heat balance has many heat transfer components, and they are all coupled. Both long-wave (LW) and short-wave (SW) radiation are important, as well as wall conduction and convection to the air. The indoor-face heat balance for each surface can be written as follows:

$$q''_{LWX} + q''_{SW} + q''_{LWS} + q''_{ki} + q''_{sol} + q''_{conv} = 0 \quad (17)$$

where

q''_{LWX} = net long-wave radiant flux exchange between zone surfaces, W/m^2
q''_{SW} = net short-wave radiation flux to surface from lights, W/m^2
q''_{LWS} = long-wave radiation flux from equipment in zone, W/m^2
q''_{ki} = conductive flux through wall, W/m^2
q''_{sol} = transmitted solar radiative flux absorbed at surface, W/m^2
q''_{conv} = convective heat flux to zone air, W/m^2

These terms are explained in the following paragraphs.

LW Radiation Exchange Among Zone Surfaces. The limiting cases for modeling internal LW radiation exchange are

- Zone air is completely transparent to LW radiation
- Zone air completely absorbs LW radiation from surfaces in the zone

Most HB models treat air as completely transparent and not participating in LW radiation exchange among surfaces in the zone. The second model is attractive because it can be formulated simply using a combined radiative and convective heat transfer coefficient from each surface to the zone air and thus decouples radiant exchange among surfaces in the zone. However, because the transparent air model allows radiant exchange and is more realistic, the second model is inferior.

Furniture in a zone increases the amount of surface area that can participate in radiative and convective heat exchanges. It also adds thermal mass to the zone. These two changes can affect the time response of the zone cooling load.

SW Radiation from Lights. The short-wavelength radiation from lights is usually assumed to be distributed over the surfaces in the zone in some manner. The HB procedure retains this approach but allows the distribution function to be changed.

LW Radiation from Internal Sources. The traditional model for this source defines a radiative/convective split for heat introduced into a zone from equipment. The radiative part is then distributed over the zone's surfaces in some manner. This model is not completely realistic, and it departs from HB principles. In a true HB model, equipment surfaces are treated just as other LW radiant sources in the zone. However, because information about the surface temperature of equipment is rarely known, it is reasonable to keep the radiative/convective split concept even though it ignores the true nature of the radiant exchange. ASHRAE research project RP-1055 (Hosni et al. 1999) determined radiative/convective splits for many additional equipment types, as listed in footnotes for Tables 8 and 9.

Transmitted Solar Heat Gain. Chapter 15's calculation procedure for determining transmitted solar energy through fenestration uses the solar heat gain coefficient (SHGC) directly rather than relating it to double-strength glass, as is done when using a shading coefficient (SC). The difficulty with this plan is that the SHGC includes both transmitted solar and inward-flowing fraction of the solar radiation absorbed in the window. With the HB method, this latter part should be added to the conduction component so it can be included in the indoor-face heat balance.

Transmitted solar radiation is also distributed over surfaces in the zone in a prescribed manner. It is possible to calculate the actual position of beam solar radiation, but this involves partial surface irradiation, which is inconsistent with the rest of the zone model, which assumes uniform conditions over an entire surface.

Using SHGC to Calculate Solar Heat Gain

The total solar heat gain through fenestration consists of directly transmitted solar radiation plus the inward-flowing fraction of solar radiation that is absorbed in the glazing system. Both parts contain beam and diffuse contributions. Transmitted radiation goes directly onto surfaces in the zone and is accounted for in the surface indoor heat balance. The zone heat balance model accommodates the resulting heat fluxes without difficulty. The second part, the inward-flowing fraction of the absorbed solar radiation, interacts with other surfaces of the enclosure through long-wave radiant exchange and with zone air through convective heat transfer. As such, it depends both on geometric and radiative properties of the zone enclosure and convection characteristics inside and outside the zone. The **solar heat gain coefficient (SHGC)** combines the transmitted solar radiation and the inward-flowing fraction of the absorbed radiation. The SHGC is defined as

$$\text{SHGC} = \tau + \sum_{k=1}^{n} N_k \alpha_k \quad (18)$$

where

τ = solar transmittance of glazing
α_k = solar absorptance of the kth layer of the glazing system
n = number of layers
N_k = inward-flowing fraction of absorbed radiation in the kth layer

Note that Equation (18) is written generically. It can be written for a specific incidence angle and/or radiation wavelength and integrated over the wavelength and/or angle, but the principle is the same in each case. Refer to Chapter 15 for the specific expressions.

Unfortunately, the inward-flowing fraction N interacts with the zone in many ways. This interaction can be expressed as

N = f(indoor convection coefficient, outdoor convection coefficient, glazing system overall heat transfer coefficient, zone geometry, zone radiation properties)

The only way to model these interactions correctly is to combine the window model with the zone heat balance model and solve both simultaneously. This has been done recently in some energy analysis programs, but is not generally available in load calculation procedures. In addition, the SHGC used for rating glazing systems is based on specific values of the indoor, outdoor, and overall heat transfer coefficients and does not include any zonal long-wavelength radiation considerations. So, the challenge is to devise a way to use SHGC values within the framework of heat balance calculation in the most accurate way possible, as discussed in the following paragraphs.

Using SHGC Data. The normal incidence SHGC used to rate and characterize glazing systems is not sufficient for determining solar heat gain for load calculations. These calculations require

Licensed for single user. © 2021, ASHRAE, Inc.

Source: LBL (2015).

solar heat gain as a function of the incident solar angle to determine the hour-by-hour gain profile. Thus, it is necessary to use angular SHGC values and also diffuse SHGC values. These can be obtained from the WINDOW 7.4.6 program (LBL 2015). This program does a detailed optical and thermal simulation of a glazing system and, when applied to a single clear layer, produces the information shown in Table 13.

Table 13 shows the parameters as a function of incident solar angle and also the diffuse values. The specific parameters shown are

V_{tc} = transmittance in visible spectrum
R_{fv} and R_{bv} = front and back surface visible reflectances
T_{sol} = solar transmittance [τ in Equations (18), (19), and (20)]
R_f and R_b = front and back surface solar reflectances
A_{bs1} = solar absorptance for layer 1, which is the only layer in this case [α in Equations (18), (19), and (20)]
SHGC = solar heat gain coefficient at center of glazing

The parameters used for heat gain calculations are T_{sol}, A_{bs}, and SHGC. For the specific convective conditions assumed in WINDOW 7.4.6 program, the inward-flowing fraction of the absorbed solar can be obtained by rearranging Equation (18) to give

$$N_k \alpha_k = \text{SHGC} - \tau \tag{19}$$

This quantity, when multiplied by the appropriate incident solar intensity, provides the amount of absorbed solar radiation that flows inward. In the heat balance formulation for zone loads, this heat flux is combined with that caused by conduction through glazing and included in the surface heat balance.

The outward-flowing fraction of absorbed solar radiation is used in the heat balance on the outdoor face of the glazing and is determined from

$$(1 - N_k)\alpha_k = \alpha_k - N_k \alpha_k = \alpha_k - (\text{SHGC} - \tau) \tag{20}$$

If there is more than one layer, the appropriate summation of absorptances must be done.

There is some potential inaccuracy in using the WINDOW 7.4.6 SHGC values because the inward-flowing fraction part was determined under specific conditions for the indoor and outdoor heat transfer coefficients. However, the program can be run with indoor and outdoor coefficients of one's own choosing. Normally, however, this effect is not large, and only in highly absorptive glazing systems might cause significant error.

For solar heat gain calculations, then, it seems reasonable to use the generic window property data that comes from WINDOW 7.4.6. Considering Table 13, the procedure is as follows:

1. Determine angle of incidence for the glazing.
2. Determine corresponding SHGC.
3. Evaluate $N_k \alpha_k$ using Equation (18).
4. Multiply T_{sol} by incident beam radiation intensity to get transmitted beam solar radiation.
5. Multiply $N_k \alpha_k$ by incident beam radiation intensity to get inward-flowing absorbed heat.
6. Repeat steps 2 to 5 with diffuse parameters and diffuse radiation.
7. Add beam and diffuse components of transmitted and inward-flowing absorbed heat.

This procedure is incorporated into the HB method so the solar gain is calculated accurately for each hour.

Table 10 in Chapter 15 contains SHGC information for many additional glazing systems. That table is similar to Table 13 but is slightly abbreviated. Again, the information needed for heat gain calculations is T_{sol}, SHGC, and A_{bs}.

The same caution about the indoor and outdoor heat transfer coefficients applies to the information in Table 10 in Chapter 15. Those values were also obtained with specific indoor and outdoor heat transfer coefficients, and the inward-flowing fraction N is dependent upon those values.

Convection to Zone Air. Indoor convection coefficients presented in past editions of this chapter and used in most load calculation procedures and energy programs are based on very old, natural convection experiments and do not accurately describe heat transfer coefficients in a mechanically ventilated zone. In previous load calculation procedures, these coefficients were buried in the procedures and could not be changed. A heat balance formulation keeps them as working parameters. In this way, research results such as those from ASHRAE research project RP-664 (Fisher 1998) can be incorporated into the procedures. It also allows determining the sensitivity of the load calculation to these parameters.

Air Heat Balance

In HB formulations aimed at determining cooling loads, the capacitance of air in the zone is neglected and the air heat balance is done as a quasisteady balance in each time period. Four factors contribute to the air heat balance:

$$q_{conv} + q_{CE} + q_{IV} + q_{sys} = 0 \tag{21}$$

where

q_{conv} = convective heat transfer from surfaces, W
q_{CE} = convective parts of internal loads, W
q_{IV} = sensible load caused by infiltration and ventilation air, W
q_{sys} = heat transfer to/from HVAC system, W

Convection from zone surfaces q_{conv} is the sum of all the convective heat transfer quantities from the indoor-surface heat balance. This comes to the air through the convective heat transfer coefficient on the surfaces.

The **convective parts of the internal loads q_{CE}** is the companion to q''_{LWS}, the radiant contribution from internal loads [Equation (17)]. It is added directly to the air heat balance. This also violates the tenets of the HB approach, because surfaces producing internal

Licensed for single user. © 2021, ASHRAE, Inc.

loads exchange heat with zone air through normal convective processes. However, once again, this level of detail is generally not included in the heat balance, so it is included directly into the air heat balance instead.

In keeping with the well-mixed model for zone air, any air that enters directly to a space through **infiltration or ventilation** q_{IV} is immediately mixed with the zone's air. The amount of infiltration or natural ventilation air is uncertain. Sometimes it is related to the indoor/outdoor temperature difference and wind speed; however it is determined, it is added directly to the air heat balance.

Conditioned air that enters the zone from the HVAC system and provides q_{sys} is also mixed directly with the zone air. For commercial HVAC systems, ventilation air is most often provided using outdoor air as part of this mixed-in conditioned air; ventilation air is thus normally a system load rather than a direct-to-space load. An exception is where infiltration or natural ventilation is used to provide all or part of the ventilation air, as discussed in Chapter 16.

5.3 GENERAL ZONE FOR LOAD CALCULATION

The HB procedure is tailored to a single thermal zone, shown in Figure 7. The definition of a thermal zone depends on how the fixed temperature is controlled. If air circulated through an entire building or an entire floor is uniformly well stirred, the entire building or floor could be considered a thermal zone. On the other hand, if each room has a different control scheme, each room may need to be considered as a separate thermal zone. The framework needs to be flexible enough to accommodate any zone arrangement, but the heat balance aspect of the procedure also requires that a complete zone be described. This zone consists of four walls, a roof or ceiling, a floor, and a "thermal mass surface" (described in the section on Input Required). Each wall and the roof can include a window (or skylight in the case of the roof). This makes a total of 12 surfaces, any of which may have zero area if it is not present in the zone to be modeled.

The heat balance processes for this general zone are formulated for a 24 h steady-periodic condition. The variables are the indoor and outdoor temperatures of the 12 surfaces plus either the HVAC system energy required to maintain a specified air temperature or the air temperature, if system capacity is specified. This makes a total of 25 × 24 = 600 variables. Although it is possible to set up the problem for a simultaneous solution of these variables, the relatively weak coupling of the problem from one hour to the next allows a double iterative approach. One iteration is through all the surfaces in each hour, and the other is through the 24 h of a day. This procedure automatically reconciles nonlinear aspects of surface radiative exchange and other heat flux terms.

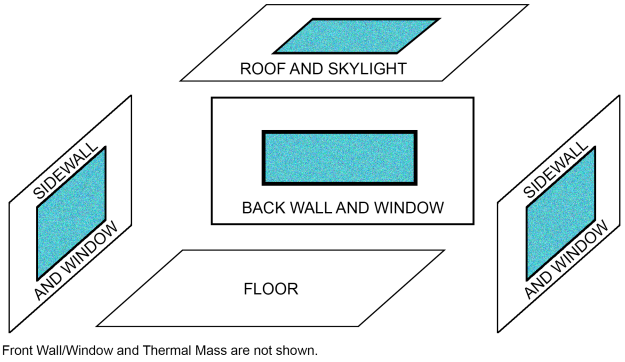

Fig. 7 Schematic View of General Heat Balance Zone

5.4 MATHEMATICAL DESCRIPTION

Conduction Process

Because it links the outdoor and indoor heat balances, the wall conduction process regulates the cooling load's time dependence. For the HB procedure presented here, wall conduction is formulated using **conduction transfer functions (CTFs)**, which relate conductive heat fluxes to current and past surface temperatures and past heat fluxes. The general form for the indoor heat flux is

$$q''_{ki}(t) = -Z_o T_{si,\theta} - \sum_{j=1}^{nz} Z_j T_{si,\theta-j\delta} + Y_o T_{so,\theta} + \sum_{j=1}^{nz} Y_j T_{so,\theta-j\delta} + \sum_{j=1}^{nq} \Phi_j q''_{ki,\theta-j\delta} \quad (22)$$

For outdoor heat flux, the form is

$$q''_{ko}(t) = -Y_o T_{si,\theta} - \sum_{j=1}^{nz} Y_j T_{si,\theta-j\delta} + X_o T_{so,\theta} + \sum_{j=1}^{nz} X_j T_{so,\theta-j\delta} + \sum_{j=1}^{nq} \Phi_j q''_{ko,\theta-j\delta} \quad (23)$$

where

X_j = outdoor CTF, $j = 0,1,\ldots nz$
Y_j = cross CTF, $j = 0,1,\ldots nz$
Z_j = indoor CTF, $j = 0,1,\ldots nz$
Φ_j = flux CTF, $j = 1,2,\ldots nq$
θ = time
δ = time step
T_{si} = indoor-face temperature, °C
T_{so} = outdoor-face temperature, °C
q''_{ki} = conductive heat flux on indoor face, W/m²
q''_{ko} = conductive heat flux on outdoor face, W/m²

The subscript following the comma indicates the time period for the quantity in terms of time step δ. Also, the first terms in the series have been separated from the rest to facilitate solving for the current temperature in the solution scheme.

The two summation limits nz and nq depend on wall construction and also somewhat on the scheme used for calculating the CTFs. If $nq = 0$, the CTFs are generally referred to as **response factors**, but then theoretically nz is infinite. Values for nz and nq are generally set to minimize the amount of computation. A development of CTFs can be found in Hittle and Pedersen (1981).

Heat Balance Equations

The primary variables in the heat balance for the general zone are the 12 indoor face temperatures and the 12 outdoor face temperatures at each of the 24 h, assigning i as the surface index and j as the hour index, or, in the case of CTFs, the sequence index. Thus, the primary variables are

$T_{so_{i,j}}$ = outdoor face temperature, $i = 1,2,\ldots,12$; $j = 1,2,\ldots, 24$

$T_{si_{i,j}}$ = indoor face temperature, $i = 1,2,\ldots,12$; $j = 1,2,\ldots, 24$

In addition, q_{sys_j} = cooling load, $j = 1,2,\ldots, 24$.

Equations (16) and (23) are combined and solved for T_{so} to produce 12 equations applicable in each time step:

Licensed for single user. © 2021, ASHRAE, Inc.

$$T_{so_{i,j}} = \left(\sum_{k=1}^{nz} T_{si_{i,j-k}} Y_{i,k} - \sum_{k=1}^{nz} T_{so_{i,j-k}} Z_{i,k} - \sum_{k=1}^{nq} \Phi_{i,k} q''_{ko_{i,j-k}} + q''_{\alpha sol_{i,j}} + q''_{LWR_{i,j}} + T_{si_{i,j}} Y_{i,0} + T_{o_j} h_{co_{i,j}} \right) / (X_{i,0} + h_{co_{i,j}}) \quad (24)$$

where

T_o = outdoor air temperature
h_{co} = outdoor convection coefficient, introduced by using $q''_{conv} = h_{co}(T_o - T_{so})$

Equation (24) shows the need to separate $X_{i,0}$, because the contribution of current surface temperature to conductive flux cannot be collected with the other historical terms involving that temperature.

Equations (17) and (22) are combined and solved for T_{si} to produce the next 12 equations:

$$T_{si_{i,j}} = \left(T_{so_{i,j}} Y_{i,0} + \sum_{k-1}^{nz} T_{so_{i,j-k}} Y_{i,k} - \sum_{k=1}^{nz} T_{si_{i,j-k}} Z_{i,k} + \sum_{k=1}^{nq} \Phi_{i,k} q''_{ki_{i,j-k}} + T_{a_j} h_{ci_j} + q''_{LWS} + q''_{LWX} + q''_{SW} + q''_{sol\,e} \right) / (Z_{i,0} + h_{ci_{i,j}}) \quad (25)$$

where

T_a = zone air temperature
h_{ci} = convective heat transfer coefficient indoors, obtained from $q''_{conv} = h_{ci}(T_a - T_{si})$

Note that in Equations (24) and (25), the opposite surface temperature at the current time appears on the right-hand side. The two equations could be solved simultaneously to eliminate those variables. Depending on the order of updating the other terms in the equations, this can have a beneficial effect on solution stability.

The remaining equation comes from the air heat balance, Equation (21). This provides the cooling load q_{sys} at each time step:

$$q_{sys_j} = \sum_{i=1}^{12} A_i h_{ci} (T_{si_{i,j}} - T_{a_j}) + q_{CE} + q_{IV} \quad (26)$$

In Equation (26), the convective heat transfer term is expanded to show the interconnection between the surface temperatures and the cooling load.

Overall HB Iterative Solution

The iterative HB procedure consists of a series of initial calculations that proceed sequentially, followed by a double iteration loop, as shown in the following steps:

1. Initialize areas, properties, and face temperatures for all surfaces, 24 h.
2. Calculate incident and transmitted solar flux for all surfaces and hours.
3. Distribute transmitted solar energy to all indoor faces, 24 h.
4. Calculate internal load quantities for all 24 h.
5. Distribute LW, SW, and convective energy from internal loads to all surfaces for all hours.
6. Calculate infiltration and direct-to-space ventilation loads for all hours.
7. Iterate the heat balance according to the following scheme:

```
For Day = 1 to Maxdays
    For j = 1 to 24                    {hours in the day}
        For SurfaceIter = 1 to MaxIter
            For i = 1 to 12            {The twelve zone surfaces}
                Evaluate Equations (33) and (34)
            Next i
        Next SurfaceIter
        Evaluate Equation (35)
    Next j
If not converged, Next Day
```

8. Display results.

Generally, four or six surface iterations are sufficient to provide convergence. The convergence check on the day iteration should be based on the difference between the indoor and outdoor conductive heat flux terms q_k. A limit, such as requiring the difference between all indoor and outdoor flux terms to be less than 1% of either flux, works well.

5.5 INPUT REQUIRED

Previous methods for calculating cooling loads attempted to simplify the procedure by precalculating representative cases and grouping the results with various correlating parameters. This generally tended to reduce the amount of information required to apply the procedure. With heat balance, no precalculations are made, so the procedure requires a fairly complete description of the zone.

Global Information. Because the procedure incorporates a solar calculation, some global information is required, including latitude, longitude, time zone, month, day of month, directional orientation of the zone, and zone height (floor to floor). Additionally, to take full advantage of the flexibility of the method to incorporate, for example, variable outdoor heat transfer coefficients, things such as wind speed, wind direction, and terrain roughness may be specified. Normally, these variables and others default to some reasonable set of values, but the flexibility remains.

Wall Information (Each Wall). Because the walls are involved in three of the fundamental processes (external and internal heat balance and wall conduction), each wall of the zone requires a fairly large set of variables. They include

- Facing angle with respect to solar exposure
- Tilt (degrees from horizontal)
- Area
- Solar absorptivity outdoors
- Long-wave emissivity outdoors
- Short-wave absorptivity indoors
- Long-wave emissivity indoors
- Exterior boundary temperature condition (solar versus nonsolar)
- External roughness
- Layer-by-layer construction information

Again, some of these parameters can be defaulted, but they are changeable, and they indicate the more fundamental character of the HB method because they are related to true heat transfer processes.

Window Information (Each Window). The situation for windows is similar to that for walls, but the windows require some additional information because of their role in the solar load. Necessary parameters include

- Area
- Normal solar transmissivity
- Normal SHGC
- Normal total absorptivity
- Long-wave emissivity outdoors
- Long-wave emissivity indoor
- Surface-to-surface thermal conductance

Licensed for single user. © 2021, ASHRAE, Inc.

- Reveal (for solar shading)
- Overhang width (for solar shading)
- Distance from overhang to window (for solar shading)

Roof and Floor Details. The roof and floor surfaces are specified similarly to walls. The main difference is that the ground outdoor boundary condition will probably be specified more often for a floor.

Thermal Mass Surface Details. An "extra" surface, called a thermal mass surface, can serve several functions. It is included in radiant heat exchange with the other surfaces in the space but is only exposed to the indoor air convective boundary condition. As an example, this surface would be used to account for movable partitions in a space. Partition construction is specified layer by layer, similar to specification for walls, and those layers store and release heat by the same conduction mechanism as walls. As a general definition, the extra thermal mass surface should be sized to represent all surfaces in the space that are exposed to the air mass, except the walls, roof, floor, and windows. In the formulation, both sides of the thermal mass participate in the exchange.

Internal Heat Gain Details. The space can be subjected to several internal heat sources: people, lights, electrical equipment, and infiltration. Infiltration energy is assumed to go immediately into the air heat balance, so it is the least complicated of the heat gains. For the others, several parameters must be specified. These include the following fractions:

- Sensible heat gain
- Latent heat gain
- Short-wave radiation
- Long-wave radiation
- Energy that enters the air immediately as convection
- Activity level of people
- Lighting heat gain that goes directly to the return air

Radiant Distribution Functions. As mentioned previously, the generally accepted assumptions for the HB method include specifying the distribution of radiant energy from several sources to surfaces that enclose the space. This requires a distribution function that specifies the fraction of total radiant input absorbed by each surface. The types of radiation that require distribution functions are

- Long-wave, from equipment and lights
- Short-wave, from lights
- Transmitted solar

Other Required Information. Additional flexibility is included in the model so that results of research can be incorporated easily. This includes the capability to specify such things as

- Heat transfer coefficients/convection models
- Solar coefficients
- Sky models

The amount of input information required may seem extensive, but many parameters can be set to default values in most routine applications. However, all parameters listed can be changed when necessary to fit unusual circumstances or when additional information is obtained.

6. RADIANT TIME SERIES (RTS) METHOD

The radiant time series (RTS) method is a simplified method for performing design cooling load calculations that is derived from the heat balance (HB) method. It effectively replaces all other simplified (non-heat-balance) methods, such as the transfer function method (TFM), the cooling load temperature difference/cooling load factor (CLTD/CLF) method, and the total equivalent temperature difference/time averaging (TETD/TA) method.

This method was developed to offer an approach that is rigorous, yet does not require iterative calculations, and that quantifies each component's contribution to the total cooling load. In addition, it is desirable for the user to be able to inspect and compare the coefficients for different construction and zone types in a form showing their relative effect on the result. These characteristics of the RTS method make it easier to apply engineering judgment during cooling load calculation.

The RTS method is suitable for peak design load calculations, but it should not be used for annual energy simulations because of its inherent limiting assumptions. Although simple in concept, RTS involves too many calculations for practical use as a manual method, although it can easily be implemented in a simple computerized spreadsheet, as shown in the examples. For a manual cooling load calculation method, refer to the CLTD/CLF method in Chapter 28 of the 1997 *ASHRAE Handbook—Fundamentals*.

6.1 ASSUMPTIONS AND PRINCIPLES

Design cooling loads are based on the assumption of **steady-periodic conditions (**i.e., the design day's weather, occupancy, and heat gain conditions are identical to those for preceding days such that the loads repeat on an identical 24 h cyclical basis). Thus, the heat gain for a particular component at a particular hour is the same as 24 h prior, which is the same as 48 h prior, etc. This assumption is the basis for the RTS derivation from the HB method.

Cooling load calculations must address two time-delay effects inherent in building heat transfer processes:

- Delay of conductive heat gain through opaque massive exterior surfaces (walls, roofs, or floors)
- Delay of radiative heat gain conversion to cooling loads.

Exterior walls and roofs conduct heat because of temperature differences between outdoor and indoor air. In addition, solar energy on exterior surfaces is absorbed, then transferred by conduction to the building interior. Because of the mass and thermal capacity of the wall or roof construction materials, there is a substantial time delay in heat input at the exterior surface becoming heat gain at the interior surface.

As described in the section on Cooling Load Principles, most heat sources transfer energy to a room by a combination of convection and radiation. The convective part of heat gain immediately becomes cooling load. The radiative part must first be absorbed by the finishes and mass of the interior room surfaces, and becomes cooling load only when it is later transferred by convection from those surfaces to the room air. Thus, radiant heat gains become cooling loads over a delayed period of time.

6.2 OVERVIEW

Figure 8 gives an overview of the RTS method. When calculating solar radiation, transmitted solar heat gain through windows, sol-air temperature, and infiltration, RTS is exactly the same as previous simplified methods (TFM and TETD/TA). Important areas that differ from previous simplified methods include

- Computation of conductive heat gain
- Splitting of all heat gains into radiant and convective portions
- Conversion of radiant heat gains into cooling loads

The RTS method accounts for both conduction time delay and radiant time delay effects by multiplying hourly heat gains by 24 h time series. The time series multiplication, in effect, distributes heat gains over time. Series coefficients, which are called **radiant time factors** and **conduction time factors**, are derived using the HB method. Radiant time factors reflect the percentage of an earlier

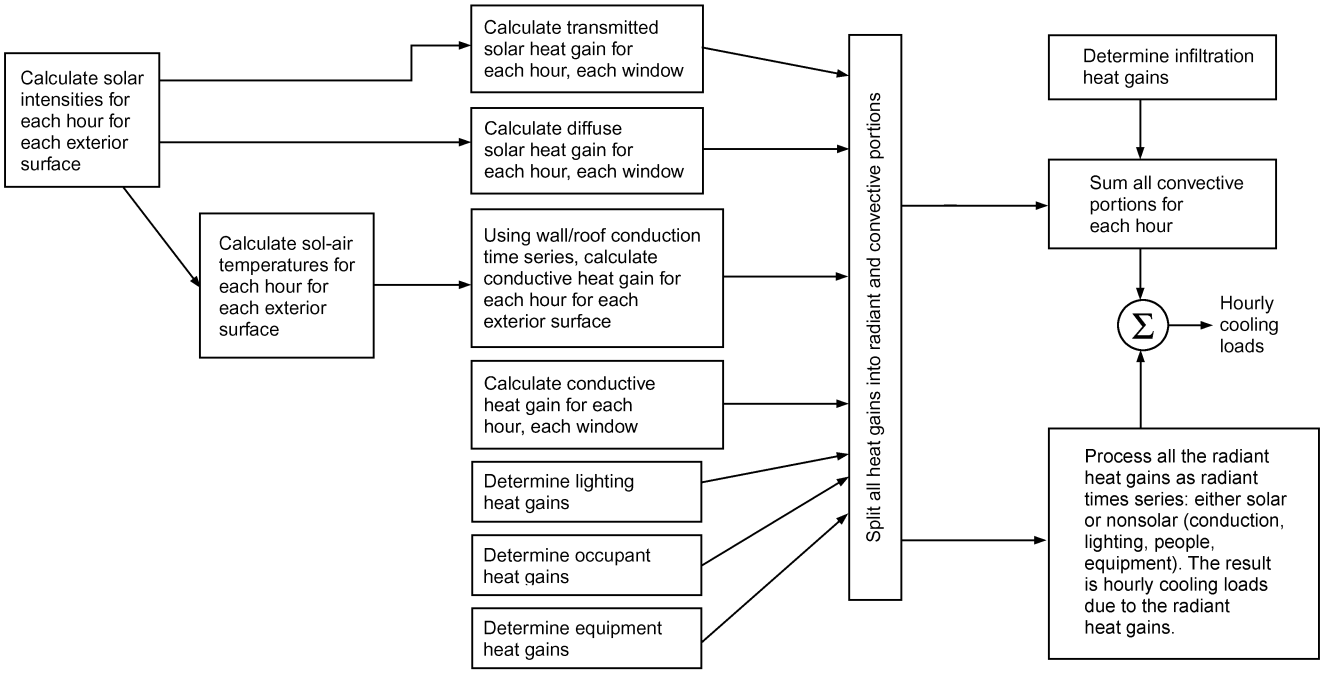

Fig. 8 Overview of Radiant Time Series Method

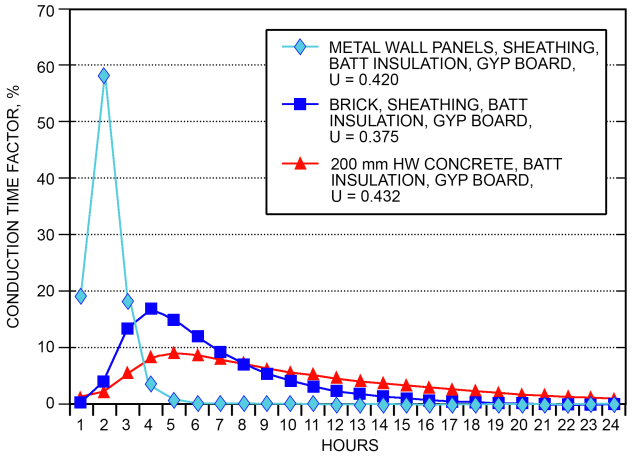

Fig. 9 CTS for Light to Heavy Walls

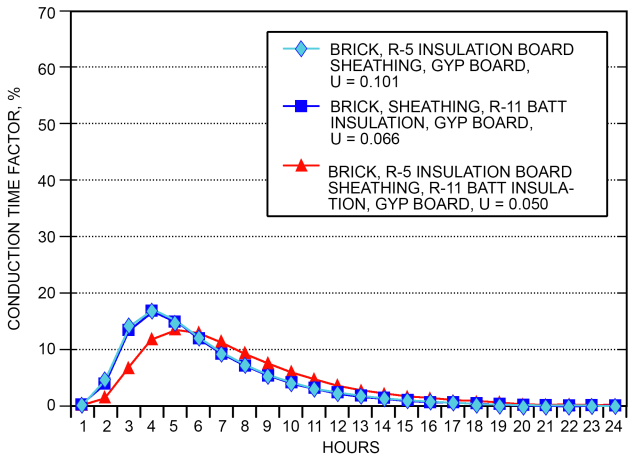

Fig. 10 CTS for Walls with Similar Mass and Increasing Insulation

radiant heat gain that becomes cooling load during the current hour. Likewise, conduction time factors reflect the percentage of an earlier heat gain at the exterior of a wall or roof that becomes heat gain indoors during the current hour. By definition, each radiant or conduction time series must total 100%.

These series can be used to easily compare the time-delay effect of one construction versus another. This ability to compare choices is of particular benefit during design, when all construction details may not have been decided. Comparison can show the magnitude of difference between the choices, allowing the engineer to apply judgment and make more informed assumptions in estimating the load.

Figure 9 shows conduction time series (CTS) values for three walls with similar U-factors but with light to heavy construction. Figure 10 shows CTS for three walls with similar construction but with different amounts of insulation, thus with significantly different U-factors. Figure 11 shows RTS values for zones varying from light to heavy construction.

6.3 RTS PROCEDURE

The general procedure for calculating cooling load for each load component (lights, people, walls, roofs, windows, appliances, etc.) with RTS is as follows:

1. Calculate 24 h profile of component heat gains for design day (for conduction, first account for conduction time delay by applying conduction time series).
2. Split heat gains into radiant and convective parts (see Table 14 for radiant and convective fractions).
3. Apply appropriate radiant time series to radiant part of heat gains to account for time delay in conversion to cooling load.
4. Sum convective part of heat gain and delayed radiant part of heat gain to determine cooling load for each hour for each cooling load component.

After calculating cooling loads for each component for each hour, sum those to determine the total cooling load for each hour and select the hour with the peak load for design of the air-conditioning system. Repeat this process for multiple design months to determine the month when the peak load occurs, especially with windows on southern exposures (northern exposure in southern latitudes), which can result in higher peak room cooling loads in winter months than in summer.

6.4 HEAT GAIN THROUGH EXTERIOR SURFACES

Heat gain through exterior opaque surfaces is derived from the same elements of solar radiation and thermal gradient as that for fenestration areas. It differs primarily as a function of the mass and nature of the wall or roof construction, because those elements affect the rate of conductive heat transfer through the composite assembly to the interior surface.

Sol-Air Temperature

Sol-air temperature is the outdoor air temperature that, in the absence of all radiation changes gives the same rate of heat entry into the surface as would the combination of incident solar radiation, radiant energy exchange with the sky and other outdoor surroundings, and convective heat exchange with outdoor air.

Heat Flux into Exterior Sunlit Surfaces. The heat balance at a sunlit surface gives the heat flux into the surface q/A as

$$\frac{q}{A} = \alpha E_t + h_o(t_o - t_s) - \varepsilon \Delta R \tag{27}$$

where

α = absorptance of surface for solar radiation
E_t = total solar radiation incident on surface, W/m^2
h_o = coefficient of heat transfer by long-wave radiation and convection at outer surface, W/(m^2·K)
t_o = outdoor air temperature, °C
t_s = surface temperature, °C
ε = hemispherical emittance of surface
ΔR = difference between long-wave radiation incident on surface from sky and surroundings and radiation emitted by blackbody at outdoor air temperature, W/m^2

Assuming the rate of heat transfer can be expressed in terms of the sol-air temperature t_e,

$$\frac{q}{A} = h_o(t_e - t_s) \tag{28}$$

and from Equations (27) and (28),

$$t_e = t_o + \frac{\alpha E_t}{h_o} - \frac{\varepsilon \Delta R}{h_o} \tag{29}$$

For **horizontal surfaces** that receive long-wave radiation from the sky only, an appropriate value of ΔR is about 63 W/m^2, so that if $\varepsilon = 1$ and $h_o = 17$ W/(m^2·K), the long-wave correction term is about 4 K (Bliss 1961).

Because **vertical surfaces** receive long-wave radiation from the ground and surrounding buildings as well as from the sky, accurate ΔR values are difficult to determine. When solar radiation intensity is high, surfaces of terrestrial objects usually have a higher temperature than the outdoor air; thus, their long-wave radiation compensates to some extent for the sky's low emittance. Therefore, it is common practice to assume $\varepsilon \Delta R = 0$ for vertical surfaces.

Tabulated Temperature Values. The sol-air temperatures in Example Cooling and Heating Load Calculations section have been calculated based on $\varepsilon \Delta R/h_o$ values of 4 K for horizontal surfaces and 0 K for vertical surfaces; total solar intensity values used for the calculations were calculated using equations in Chapter 14.

Surface Colors. Sol-air temperature values are given in the Example Cooling and Heating Load Calculations section for two values of the parameter α/h_o; the value of 0.026 is appropriate for a

light-colored surface, whereas 0.052 represents the usual maximum value for this parameter (i.e., for a dark-colored surface or any surface for which the permanent lightness cannot reliably be anticipated). Solar absorptance values of various surfaces are included in Table 15.

This procedure was used to calculate the sol-air temperatures included in the Examples section. Because of the tedious solar angle and intensity calculations, using a simple computer spreadsheet or other software for these calculations can reduce the effort involved.

Calculating Conductive Heat Gain Using Conduction Time Series

In the RTS method, conduction through exterior walls and roofs is calculated using CTS values. Wall and roof conductive heat input at the exterior is defined by the familiar conduction equation as

$$q_{i,\theta-n} = UA(t_{e,\theta-n} - t_{rc}) \quad (30)$$

where

$q_{i,\theta-n}$ = conductive heat input for surface n hours ago, W
U = overall heat transfer coefficient for surface, W/(m^2·K)
A = surface area, m^2
$t_{e,\theta-n}$ = sol-air temperature n hours ago, °C
t_{rc} = presumed constant room air temperature, °C

Conductive heat gain through walls or roofs can be calculated using conductive heat inputs for the current hours and past 23 h and conduction time series:

$$q_\theta = c_0 q_{i,\theta} + c_1 q_{i,\theta-1} + c_2 q_{i,\theta-2} + c_3 q_{i,\theta-3} + \cdots + c_{23} q_{i,\theta-23} \quad (31)$$

where

q_θ = hourly conductive heat gain for surface, W
$q_{i,\theta}$ = heat input for current hour
$q_{i,\theta-n}$ = heat input n hours ago
c_0, c_1, etc.=conduction time factors

Conduction time factors for representative wall and roof types are included in Tables 16 and 17. Those values were derived by first calculating conduction transfer functions for each example wall and roof construction. Assuming steady-periodic heat input conditions for design load calculations allows conduction transfer functions to be reformulated into periodic response factors, as demonstrated by Spitler and Fisher (1999a). The periodic response factors were further simplified by dividing the 24 periodic response factors by the respective overall wall or roof U-factor to form the conduction time series. The conduction time factors can then be used in Equation (31) and provide a way to compare time delay characteristics between different wall and roof constructions. Construction material data used in the calculations for walls and roofs in Tables 16 and 17 are listed in Table 18.

Heat gains calculated for walls or roofs using periodic response factors (and thus CTS) are identical to those calculated using conduction transfer functions for the steady periodic conditions assumed in design cooling load calculations. The methodology for calculating periodic response factors from conduction transfer functions was originally developed as part of ASHRAE research project RP-875 (Spitler and Fisher 1999b; Spitler et al. 1997). For walls and roofs that are not reasonably close to the representative constructions in Tables 16 and 17, CTS coefficients may be computed with a computer program such as that described by Iu and Fisher (2004). For walls and roofs with thermal bridges, the procedure described by Karambakkam et al. (2005) may be used to determine an equivalent wall construction, which can then be used as the basis for finding the CTS coefficients. When considering the level of detail needed to make an adequate approximation, remember that, for buildings with windows and internal heat gains, the conduction heat gains make up a relatively small part of the cooling load. For heating load calculations, the conduction heat loss may be more significant.

The tedious calculations involved make a simple computer spreadsheet or other computer software a useful labor saver.

6.5 HEAT GAIN THROUGH INTERIOR SURFACES

Whenever a conditioned space is adjacent to a space with a different temperature, heat transfer through the separating physical section must be considered. The heat transfer rate is given by

$$q = UA(t_b - t_i) \quad (32)$$

where

q = heat transfer rate, W
U = coefficient of overall heat transfer between adjacent and conditioned space, W/(m^2·K)
A = area of separating section concerned, m^2
t_b = average air temperature in adjacent space, °C
t_i = air temperature in conditioned space, °C

U-values can be obtained from Chapter 27. Temperature t_b may differ greatly from t_i. The temperature in a kitchen or boiler room, for example, may be as much as 8 to 28 K above the outdoor air temperature. Actual temperatures in adjoining spaces should be measured, when possible. Where nothing is known except that the adjacent space is of conventional construction, contains no heat sources, and itself receives no significant solar heat gain, $t_b - t_i$ may be considered the difference between the outdoor air and conditioned space design dry-bulb temperatures minus 3 K. In some cases, air temperature in the adjacent space corresponds to the outdoor air temperature or higher.

Floors

For floors directly in contact with the ground or over an underground basement that is neither ventilated nor conditioned, sensible heat transfer may be neglected for cooling load estimates because usually there is a heat loss rather than a gain. An exception is in hot climates (i.e., where average outdoor air temperature exceeds indoor design condition), where the positive soil-to-indoor temperature difference causes sensible heat gains (Rock 2005). In many climates and for various temperatures and local soil conditions, moisture transport up through slabs-on-grade and basement floors is also significant, and contributes to the latent heat portion of the cooling load.

6.6 CALCULATING COOLING LOAD

The **instantaneous cooling load** is the rate at which heat energy is convected to the zone air at a given point in time. Computation of cooling load is complicated by the radiant exchange between

surfaces, furniture, partitions, and other mass in the zone. Most heat gain sources transfer energy by both convection and radiation. Radiative heat transfer introduces a time dependency to the process that is not easily quantified. Radiation is absorbed by thermal masses in the zone and then later transferred by convection into the space. This process creates a time lag and dampening effect. The convective portion, on the other hand, is assumed to immediately become cooling load in the hour in which that heat gain occurs.

Heat balance procedures calculate the radiant exchange between surfaces based on their surface temperatures and emissivities, but they typically rely on estimated "radiative/convective splits" to determine the contribution of internal loads, including people, lighting, appliances, and equipment, to the radiant exchange. RTS further simplifies the HB procedure by also relying on an estimated radiative/convective split of wall and roof conductive heat gain instead of simultaneously solving for the instantaneous convective and radiative heat transfer from each surface, as in the HB procedure.

Thus, the cooling load for each load component (lights, people, walls, roofs, windows, appliances, etc.) for a particular hour is the sum of the convective portion of the heat gain for that hour plus the time-delayed portion of radiant heat gains for that hour and the previous 23 h. Table 14 contains recommendations for splitting each of the heat gain components into convective and radiant portions.

RTS converts the radiant portion of hourly heat gains to hourly cooling loads using radiant time factors, the coefficients of the

radiant time series. Radiant time factors are used to calculate the cooling load for the current hour on the basis of current and past heat gains. The radiant time series for a particular zone gives the time-dependent response of the zone to a single pulse of radiant energy. The series shows the portion of the radiant pulse that is convected to zone air for each hour. Thus, r_0 represents the fraction of the radiant pulse convected to the zone air in the current hour r_1 in the previous hour, and so on. The radiant time series thus generated is used to convert the radiant portion of hourly heat gains to hourly cooling loads according to the following equation:

$$Q_{r,\theta} = r_0 q_{r,\theta} + r_1 q_{r,\theta-1} + r_2 q_{r,\theta-2} + r_3 q_{r,\theta-3} + \cdots + r_{23} q_{r,\theta-23} \quad (33)$$

where

$Q_{r,\theta}$ = radiant cooling load Q_r for current hour θ, W
$q_{r,\theta}$ = radiant heat gain for current hour, W
$q_{r,\theta-n}$ = radiant heat gain n hours ago, W
r_0, r_1, etc. = radiant time factors

The radiant cooling load for the current hour, which is calculated using RTS and Equation (33), is added to the convective portion to determine the total cooling load for that component for that hour.

Radiant time factors are generated by a heat-balance-based procedure. A separate series of radiant time factors is theoretically required for each unique zone and for each unique radiant energy distribution function assumption. For most common design applications, RTS variation depends primarily on the overall massiveness of the construction and the thermal responsiveness of the surfaces the radiant heat gains strike.

One goal in developing RTS was to provide a simplified method based directly on the HB method; thus, it was deemed desirable to generate RTS coefficients directly from a heat balance. A heat balance computer program was developed to do this: Hbfort, which is included as part of *Cooling and Heating Load Calculation Principles* (Pedersen et al. 1998). The RTS procedure is described by Spitler et al. (1997). The procedure for generating RTS coefficients may be thought of as analogous to the custom weighting factor generation procedure used by DOE 2.1 (Kerrisk et al. 1981; Sowell 1988a, 1988b). In both cases, a zone model is pulsed with a heat gain. With DOE 2.1, the resulting loads are used to estimate the best values of the transfer function method weighting factors to most closely match the load profile. In the procedure described here, a unit periodic heat gain pulse is used to generate loads for a 24 h period. As long as the heat gain pulse is a unit pulse, the resulting loads are equivalent to the RTS coefficients.

Two different radiant time series are used: **solar**, for direct transmitted solar heat gain (radiant energy assumed to be distributed to the floor and furnishings only) and **nonsolar**, for all other types of heat gains (radiant energy assumed to be uniformly distributed on all internal surfaces). Nonsolar RTS apply to radiant heat gains from people, lights, appliances, walls, roofs, and floors. Also, for diffuse solar heat gain and direct solar heat gain from fenestration with indoor shading (blinds, drapes, etc.), the nonsolar RTS should be used. Radiation from those sources is assumed to be more uniformly

distributed onto all room surfaces. Effect of beam solar radiation distribution assumptions is addressed by Hittle (1999).

Representative solar and nonsolar RTS data for light, medium, and heavyweight constructions are provided in Tables 19 and 20. Those were calculated using the Hbfort computer program (Pedersen et al. 1998) with zone characteristics listed in Table 21. Customized RTS values may be calculated using the HB method where the zone is not reasonably similar to these typical zones or where more precision is desired.

ASHRAE research project RP-942 compared HB and RTS results over a wide range of zone types and input variables (Rees et al. 2000; Spitler et al. 1998). In general, total cooling loads calculated using RTS closely agreed with or were slightly higher than those of the HB method with the same inputs. The project examined more than 5000 test cases of varying zone parameters. The dominating variable was overall thermal mass, and results were grouped into lightweight, U.S. medium-weight, U.K. medium-weight, and heavyweight construction. Best agreement between RTS and HB results was obtained for light- and medium-weight construction. Greater differences occurred in heavyweight cases, with RTS generally predicting slightly higher peak cooling loads than HB. Greater differences also were observed in zones with extremely high internal radiant loads and large glazing areas or with a very lightweight exterior envelope. In this case, heat balance calculations predict that some of the internal radiant load will be transmitted to the outdoor environment and never becomes cooling load in the space. RTS does

not account for energy transfer out of the space to the environment, and thus predicted higher cooling loads.

ASHRAE research project RP-1117 built two model rooms for which cooling loads were physically measured using extensive instrumentation. The results agreed with previous simulations (Chantrasrisalai et al. 2003; Eldridge et al. 2003; Iu et al. 2003). HB calculations closely approximated measured cooling loads when provided with detailed data for the test rooms. RTS overpredicted measured cooling loads in tests with large, clear, single-glazed window areas with bare concrete floor and no furnishings or internal loads. Tests under more typical conditions (venetian blinds, carpeted floor, office-type furnishings, and normal internal loads) provided good agreement between HB, RTS, and measured loads.

7. HEATING LOAD CALCULATIONS

Techniques for estimating design heating load for commercial, institutional, and industrial applications are essentially the same as for those estimating design cooling loads for such uses, with the following exceptions:

- Temperatures outdoor conditioned spaces are generally lower than maintained space temperatures.
- Credit for solar or internal heat gains is not included
- Thermal storage effect of building structure or content is ignored.

Thermal bridging effects on wall and roof conduction are greater for heating loads than for cooling loads, and greater care must be taken to account for bridging effects on U-factors used in heating load calculations.

Heat losses (negative heat gains) are thus considered to be instantaneous, heat transfer essentially conductive, and latent heat treated only as a function of replacing space humidity lost to the exterior environment.

This simplified approach is justified because it evaluates worst-case conditions that can reasonably occur during a heating season. Therefore, the near-worst-case load is based on the following:

- Design interior and exterior conditions
- Including infiltration and/or ventilation
- No solar effect (at night or on cloudy winter days)
- Before the periodic presence of people, lights, and appliances has an offsetting effect

Typical commercial and retail spaces have nighttime unoccupied periods at a setback temperature where little to no ventilation is required, building lights and equipment are off, and heat loss is primarily through conduction and infiltration. Before being occupied, buildings are warmed to the occupied temperature (see the following discussion). During occupied time, building lights, equipment, and people cooling loads can offset conduction heat loss, although some perimeter heat may be required, leaving infiltration and ventilation as the primary heating loads. Ventilation heat load may be

offset with heat recovery equipment. These loads (conduction loss, warm-up load, and ventilation load) may not be additive when sizing building heating equipment, and it is prudent to analyze each load and their interactions to arrive at final equipment sizing for heating.

7.1 HEAT LOSS CALCULATIONS

The general procedure for calculation of design heat losses of a structure is as follows:

1. Select outdoor design conditions: temperature, humidity, and wind direction and speed.
2. Select indoor design conditions to be maintained.
3. Estimate temperature in any adjacent unheated spaces.
4. Select transmission coefficients and compute heat losses for walls, floors, ceilings, windows, doors, and foundation elements.
5. Compute heat load through infiltration and any other outdoor air introduced directly to the space.
6. Sum the losses caused by transmission and infiltration.

Outdoor Design Conditions

The ideal heating system provides enough heat to match the structure's heat loss. However, weather conditions vary considerably from year to year, and heating systems designed for the worst weather conditions on record would have a great excess of capacity most of the time. A system's failure to maintain design conditions

during brief periods of severe weather usually is not critical. However, close regulation of indoor temperature may be critical for some occupancies or industrial processes. Design temperature data and discussion of their application are given in Chapter 14. Generally, the 99% temperature values given in the tabulated weather data are used. However, caution is needed, and local conditions should always be investigated. In some locations, outdoor temperatures are commonly much lower and wind velocities higher than those given in the tabulated weather data.

Indoor Design Conditions

The main purpose of the heating system is to maintain indoor conditions that make most of the occupants comfortable. Keep in mind, however, that the purpose of heating load calculations is to

obtain data for sizing the heating system components. In many cases, the system will rarely be called upon to operate at the design conditions. Therefore, the use and occupancy of the space are general considerations from the design temperature point of view. Later, when the building's energy requirements are computed, the actual conditions in the space and outdoor environment, including internal heat gains, must be considered.

The indoor design temperature should be selected at the lower end of the acceptable temperature range, so that the heating equipment will not be oversized. Even properly sized equipment operates under partial load, at reduced efficiency, most of the time; therefore, any oversizing aggravates this condition and lowers overall system efficiency. A maximum design dry-bulb temperature of 21°C is recommended for most occupancies. The indoor design value of relative

humidity should be compatible with a healthful environment and the thermal and moisture integrity of the building envelope. A minimum relative humidity of 30% is recommended for most situations.

Calculation of Transmission Heat Losses

Exterior Surface Above Grade. All above-grade surfaces exposed to outdoor conditions (walls, doors, ceilings, fenestration, and raised floors) are treated identically, as follows:

$$q = A \times \mathrm{HF} \tag{34}$$

$$\mathrm{HF} = U\,\Delta t \tag{35}$$

where HF is the heating load factor in W/m².

Below-Grade Surfaces. An approximate method for estimating below-grade heat loss [based on the work of Latta and Boileau (1969)] assumes that the heat flow paths shown in Figure 12 can be

used to find the steady-state heat loss to the ground surface, as follows:

$$HF = U_{avg}(t_{in} - t_{gr}) \quad (36)$$

where

U_{avg} = average U-factor for below-grade surface from Equation (38) or (39), W/(m²·K)
t_{in} = below-grade space air temperature, °C
t_{gr} = design ground surface temperature from Equation (37), °C

The effect of soil heat capacity means that none of the usual external design air temperatures are suitable values for t_{gr}. Ground surface temperature fluctuates about an annual mean value by amplitude A, which varies with geographic location and surface cover. The minimum ground surface temperature, suitable for heat loss estimates, is therefore

$$t_{gr} = \bar{t}_{gr} - A \quad (37)$$

Table 21 RTS Representative Zone Construction for Tables 19 and 20

Construction Class	Exterior Wall	Roof/Ceiling	Partitions	Floor	Furnishings
Light	Steel siding, 50 mm insulation, air space, 19 mm gyp.	100 mm LW concrete, ceiling air space, acoustic tile	19 mm gyp., air space, 19 mm gyp.	Acoustic tile, ceiling air space, 100 mm LW concrete	25 mm wood @ 50% of floor area
Medium	100 mm face brick, 50 mm insulation, air space, 19 mm gyp.	100 mm HW concrete, ceiling air space, acoustic tile	19 mm gyp., air space, 19 mm gyp.	Acoustic tile, ceiling air space, 100 mm HW concrete	25 mm wood @ 50% of floor area
Heavy	100 mm face brick, 200 mm HW concrete air space, 50 mm insulation, 19 mm gyp.	200 mm HW concrete, ceiling air space, acoustic tile	19 mm gyp., 200 mm HW concrete block, 19 mm gyp.	Acoustic tile, ceiling air space, 200 mm HW concrete	25 mm wood @ 50% of floor area

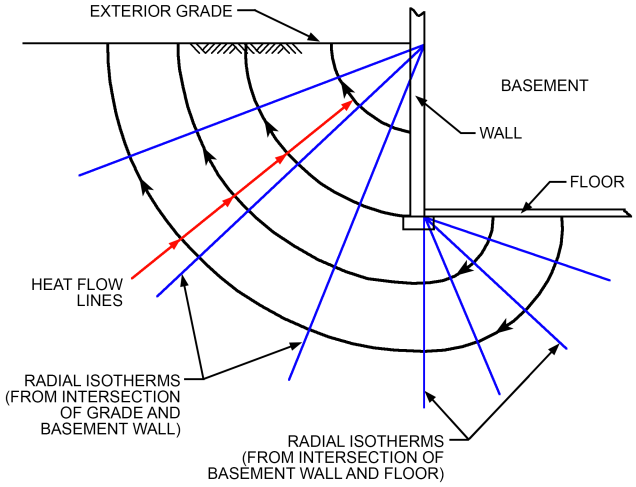

Fig. 12 Heat Flow from Below-Grade Surface

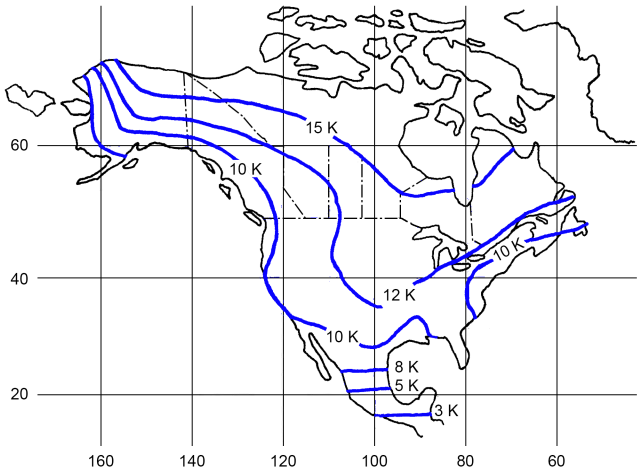

Fig. 13 Ground Temperature Amplitude

where

$\bar{t}_{gr}$ = mean ground temperature, °C, estimated from the annual average air temperature or from well-water temperatures, shown in Figure 18 of Chapter 34 in the 2011 *ASHRAE Handbook—HVAC Applications*

A = ground surface temperature amplitude, K, from Figure 13 for North America

Figure 14 shows depth parameters used in determining U_{avg}. For walls, the region defined by z_1 and z_2 may be the entire wall or any portion of it, allowing partially insulated configurations to be analyzed piecewise.

The below-grade wall average U-factor is given by

$$U_{avg,bw} = \frac{2k_{soil}}{\pi(z_2 - z_1)} \times \left[\ln\left(z_2 + \frac{2k_{soil}R_{other}}{\pi}\right) - \ln\left(z_1 + \frac{2k_{soil}R_{other}}{\pi}\right)\right] \quad (38)$$

where

$U_{avg,bw}$ = average U-factor for wall region defined by z_1 and z_2, W/(m²·K)

k_{soil} = soil thermal conductivity, W/(m·K)

R_{other} = total resistance of wall, insulation, and indoor surface resistance, (m²·K)/W

z_1, z_2 = depths of top and bottom of wall segment under consideration, m (Figure 14)

The value of soil thermal conductivity k varies widely with soil type and moisture content. A typical value of 1.4 W/(m·K) has been used previously to tabulate U-factors, and R_{other} is approximately 0.259 (m²·K)/W for uninsulated concrete walls. For these parameters, representative values for $U_{avg,bw}$ are shown in Table 22.

The average below-grade floor U-factor (where the entire basement floor is uninsulated or has uniform insulation) is given by

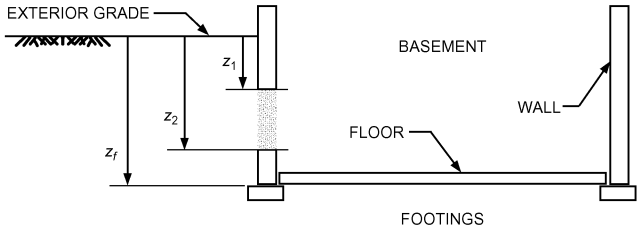

Fig. 14 Below-Grade Parameters

Table 22 Average U-Factor for Basement Walls with Uniform Insulation

Depth, m	$U_{avg,bw}$ from Grade to Depth, W/(m²·K)			
	Uninsulated	R-0.88	R-1.76	R-2.64
0.3	2.468	0.769	0.458	0.326
0.6	1.898	0.689	0.427	0.310
0.9	1.571	0.628	0.401	0.296
1.2	1.353	0.579	0.379	0.283
1.5	1.195	0.539	0.360	0.272
1.8	1.075	0.505	0.343	0.262
2.1	0.980	0.476	0.328	0.252
2.4	0.902	0.450	0.315	0.244

Soil conductivity = 1.4 W/(m·K); insulation is over entire depth. For other soil conductivities and partial insulation, use Equation (39).

$$U_{avg,bf} = \frac{2k_{soil}}{\pi w_b} \times \left[\ln\left(\frac{w_b}{2} + \frac{z_f}{2} + \frac{k_{soil}R_{other}}{\pi}\right) - \ln\left(\frac{z_f}{2} + \frac{k_{soil}R_{other}}{\pi}\right)\right] \quad (39)$$

where

w_b = basement width (shortest dimension), m

Licensed for single user. © 2021, ASHRAE, Inc.

Table 23 Average U-Factor for Basement Floors

z_f (Depth of Floor Below Grade), m	$U_{avg,bf}$, W/(m²·K)			
	w_b (Shortest Width of Basement), m			
	6	7	8	9
0.3	0.370	0.335	0.307	0.283
0.6	0.310	0.283	0.261	0.242
0.9	0.271	0.249	0.230	0.215
1.2	0.242	0.224	0.208	0.195
1.5	0.220	0.204	0.190	0.179
1.8	0.202	0.188	0.176	0.166
2.1	0.187	0.175	0.164	0.155

Soil conductivity is 1.4 W/(m·K); floor is uninsulated. For other soil conductivities and insulation, use Equation (39).

Table 24 Heat Loss Coefficient F_p of Slab Floor Construction

Construction	Insulation	F_p, W/(m·K)
200 mm block wall, brick facing	Uninsulated	1.17
	R-0.95 (m²·K)/W from edge to footer	0.86
100 mm block wall, brick facing	Uninsulated	1.45
	R-0.95 (m²·K)/W from edge to footer	0.85
Metal stud wall, stucco	Uninsulated	2.07
	R-0.95 (m²·K)/W from edge to footer	0.92
Poured concrete wall with duct near perimeter*	Uninsulated	3.67
	R-0.95 (m²·K)/W from edge to footer	1.24

*Weighted average temperature of heating duct was assumed at 43°C during heating season (outdoor air temperature less than 18°C).

z_f = floor depth below grade, m (see Figure 14)

Representative values of $U_{avg,bf}$ for uninsulated basement floors are shown in Table 23.

At-Grade Surfaces. Concrete slab floors may be (1) unheated, relying for warmth on heat delivered above floor level by the heating system, or (2) heated, containing heated pipes or ducts that constitute a radiant slab or portion of it for complete or partial heating of the house.

The simplified approach that treats heat loss as proportional to slab perimeter allows slab heat loss to be estimated for both unheated and heated slab floors:

$$q = p \times \mathrm{HF} \tag{40}$$

$$\mathrm{HF} = F_p \Delta t \tag{41}$$

where

q = heat loss through perimeter, W
F_p = heat loss coefficient per metre of perimeter, W/(m·K), Table 24
p = perimeter (exposed edge) of floor, m

Surfaces Adjacent to Buffer Space. Heat loss to adjacent unconditioned or semiconditioned spaces can be calculated using a heating factor based on the partition temperature difference:

$$\mathrm{HF} = U(t_{in} - t_b) \tag{42}$$

Infiltration

Infiltration of outdoor air through openings into a structure is caused by thermal forces, wind pressure, and negative pressure (planned or unplanned) with respect to the outdoors created by mechanical systems. Typically, in building design, if the mechanical systems are designed to maintain positive building pressure, infiltration need not be considered except in ancillary spaces such as entryways and loading areas.

Infiltration is treated as a room load and has both sensible and latent components. During winter, this means heat and humidity loss because cold, dry air must be heated to design temperature and moisture must be added to increase the humidity to design condition. Typically, during winter, controlling indoor humidity is not a factor and infiltration is reduced to a simple sensible component. Under cooling conditions, both sensible and latent components are added to the space load to be treated by the air conditioning system.Procedures for estimating the infiltration rate are discussed in Chapter 16. The infiltration rate is reduced to a volumetric flow rate at a known dry bulb/wet bulb condition. Along with indoor air condition, the following equations define the infiltration sensible and latent loads.

$$q_s(\mathrm{kW}) = [(\mathrm{m^3/s})/v]c_p(t_{in} - t_o) \tag{43}$$

where

$\mathrm{m^3/s}$ = volume flow rate of infiltrating air
c_p = specific heat capacity of air, kJ/(kg·K)
v = specific volume of infiltrating air, $\mathrm{m^3/kg}$

Assuming standard air conditions (15°C and sea-level conditions) for v and c_p, Equation (43) may be written as

$$q_s(\mathrm{kW}) = 1.23(\mathrm{m^3/s})(t_{in} - t_o) \tag{44}$$

The infiltrating air also introduces a latent heating load given by

$$q_l(\mathrm{kW}) = [(\mathrm{m^3/s})/v](W_{in} - W_o)D_h \tag{45}$$

where

W_{in} = humidity ratio for indoor space air, $\mathrm{kg_w/kg_a}$
W_o = humidity ratio for outdoor air, $\mathrm{kg_w/kg_a}$
D_h = change in enthalpy to convert 1 kg water from vapor to liquid, kJ/kg

For standard air and nominal indoor comfort conditions, the latent load may be expressed as

$$q_l = 3010(\mathrm{m^3/s})(W_{in} - W_o) \tag{46}$$

The coefficients 1.23 in Equation (44) and 3010 in Equation (46) are given for standard conditions. They depend on temperature and altitude (and, consequently, pressure).

7.2 HEATING SAFETY FACTORS AND LOAD ALLOWANCES

Before mechanical cooling became common in the second half of the 1900s, and when energy was less expensive, buildings included much less insulation; large, operable windows; and generally more infiltration-prone assemblies than the energy-efficient and much tighter buildings typical of today. Allowances of 10 to 20% of the net calculated heating load for piping losses to unheated spaces, and 10 to 20% more for a warm-up load, were common practice, along with other occasional safety factors reflecting the experience and/or concern of the individual designer. Such measures are less conservatively applied today with newer construction. A combined warm-up/safety allowance of 20 to 25% is fairly common but varies depending on the particular climate, building use, and type of construction. Engineering judgment must be applied for the particular project. Armstrong et al. (1992a, 1992b) provide a design method to deal with warm-up and cooldown load.

7.3 OTHER HEATING CONSIDERATIONS

Calculation of design heating load estimates has essentially become a subset of the more involved and complex estimation of cooling loads for such spaces. Chapter 19 discusses using the heating load estimate to predict or analyze energy consumption over time. Special provisions to deal with particular applications are covered in the 2019 *ASHRAE Handbook—HVAC Applications* and the 2020 *ASHRAE Handbook—HVAC Systems and Equipment*.

The 1989 *ASHRAE Handbook—Fundamentals* was the last edition to contain a chapter dedicated only to heating load. Its contents were incorporated into this volume's Chapter 17, which describes

steady-state conduction and convection heat transfer and provides, among other data, information on losses through basement floors and slabs.

8. SYSTEM HEATING AND COOLING LOAD EFFECTS

The heat balance (HB) or radiant time series (RTS) methods are used to determine cooling loads of rooms within a building, but they do not address the plant size necessary to reject the heat. Principal factors to consider in determining the plant size are ventilation, heat transport equipment, and air distribution systems. Some of these factors vary as a function of room load, ambient temperature, and control strategies, so it is often necessary to evaluate the factors and strategies dynamically and simultaneously with the heat loss or gain calculations.

Detailed analysis of system components and methods calculating their contribution to equipment sizing are beyond the scope of this chapter, which is general in nature. Table 25 lists the most frequently used calculations in other chapters and volumes.

8.1 ZONING

Organization of building rooms into zones as defined for load calculations and air-handling units has no effect on room cooling loads. However, specific grouping and ungrouping of rooms into zones may cause peak system loads to occur at different times during the day or year, and may significantly affect heat removal equipment sizes.

For example, if each room is cooled by a separate heat removal system, the total capacity of the heat transport systems equals the sum of peak room loads. Conditioning all rooms by a single heat transport system (e.g., a variable-volume air handler) requires less capacity (equal to the simultaneous peak of the combined rooms load, which includes some rooms at off-peak loads). This may significantly reduce equipment capacity, depending on the configuration of the building.

8.2 VENTILATION

Consult ASHRAE *Standard* 62.1 and building codes to determine the required quantity of ventilation air for an application, and the various methods of achieving acceptable indoor air quality. The following discussion is confined to the effect of mechanical ventilation on sizing heat removal equipment. Where natural ventilation is used, through operable windows or other means, it is considered as infiltration and is part of the direct-to-room heat gain. Where ventilation air is conditioned and supplied through the mechanical system, its sensible and latent loads are applied directly to heat transport and central equipment, and do not affect room heating and cooling loads. If the mechanical ventilation rate sufficiently exceeds exhaust airflows, air pressure may be positive and infiltration from envelope openings and outdoor wind may not be included in the load calculations. Chapter 16 includes more information on ventilating commercial buildings.

Depending on ventilation requirements and local climate conditions, peak cooling coil loads may occur at peak dehumidification or enthalpy conditions instead of design dry-bulb conditions. Coil loads should be checked against all those peak conditions.

8.3 AIR HEAT TRANSPORT SYSTEMS

Heat transport equipment is usually selected to provide adequate heating or cooling for the peak load condition. However, selection must also consider maintaining desired indoor conditions during all occupied hours, which requires matching the rate of heat transport to room peak heating and cooling loads. Automatic control systems normally vary the heating and cooling system capacity during these off-peak hours of operation.

On/Off Control Systems

On/off control systems, common in residential and light commercial applications, cycle equipment on and off to match room load. They are adaptable to heating or cooling because they can cycle both heating and cooling equipment. In their purest form, their heat transport matches the combined room and ventilation load over a series of cycles.

Variable-Air-Volume Systems

Variable-air-volume (VAV) systems have airflow controls that adjust cooling airflow to match the room cooling load. Damper leakage or minimum airflow settings may cause overcooling, so most VAV systems are used in conjunction with separate heating systems. These may be duct-mounted heating coils, or separate radiant or convective heating systems.

The amount of heat added by the heating systems during cooling becomes part of the room cooling load. Calculations must determine the minimum airflow relative to off-peak cooling loads. The quantity of heat added to the cooling load can be determined for each terminal by Equation (8) using the minimum required supply airflow rate and the difference between supply air temperature and the room indoor heating design temperature.

Constant-Air-Volume Reheat Systems

In constant-air-volume (CAV) reheat systems, all supply air is cooled to remove moisture and then heated to avoid overcooling rooms. *Reheat* refers to the amount of heat added to cooling supply air to raise the supply air temperature to the temperature necessary for picking up the sensible load. The quantity of heat added can be determined by Equation (8).

With a constant-volume reheat system, heat transport system load does not vary with changes in room load, unless the cooling coil discharge temperature is allowed to vary. Where a minimum circulation rate requires a supply air temperature greater than the available design supply air temperature, reheat adds to the cooling load on the heat transport system. This makes the cooling load on the heat transport system larger than the room peak load.

Mixed Air Systems

Mixed air systems change the supply air temperature to match the cooling capacity by mixing airstreams of different temperatures; examples include multizone and dual-duct systems. Systems that cool the entire airstream to remove moisture and to reheat some of the air before mixing with the cooling airstream influence load on the heat transport system in the same way a reheat system does. Other systems separate the air paths so that mixing of hot- and cold-deck airstreams does not occur. For systems that mix hot and cold airstreams, the contribution to the heat transport system load is determined as follows.

Licensed for single user. © 2021, ASHRAE, Inc.

1. Determine the ratio of cold-deck flow to hot-deck flow from

$$\frac{Q_h}{Q_c} = (T_c - T_r)/(T_r - T_h)$$

2. From Equation (9), the hot-deck contribution to room load during off-peak cooling is

$$q_{rh} = 1.23 Q_h (T_h - T_r)$$

where

Q_h = heating airflow, L/s
Q_c = cooling airflow, L/s
T_c = cooling air temperature, °C
T_h = heating air temperature, °C
T_r = room or return air temperature, °C
q_{rh} = heating airflow contribution to room load at off-peak hours, W

Heat Gain from Fans

Fans that circulate air through HVAC systems add energy to the system through the following processes:

- Increasing velocity and static pressure adds kinetic and potential energy
- Fan inefficiency in producing airflow and static pressure adds sensible heat (fan heat) to the airflow
- Inefficiency of motor and drive dissipates sensible heat

The power required to provide airflow and static pressure can be determined from the first law of thermodynamics with the following equation:

$$P_A = 0.009804 Vp$$

where

P_A = air power, kW
V = flow rate, m^3/s
p = pressure, kPa

at standard air conditions with air density = 1.2 kg/m^3 built into the multiplier 0.009804. The power necessary at the fan shaft must account for fan inefficiencies, which may vary from 50 to 70%. This may be determined from

$$P_F = P_A / \eta_F$$

where

P_F = power required at fan shaft, kW
η_F = fan efficiency, dimensionless

The power necessary at the input to the fan motor must account for fan motor inefficiencies and drive losses. Fan motor efficiencies generally vary from 80 to 95%, and drive losses for a belt drive are 3% of the fan power. This may be determined from

$$P_M = (1 + \mathrm{DL})\, P_F / E_M E_D$$

where

P_M = power required at input to motor, kW
E_D = belt drive efficiency, dimensionless
E_M = fan motor efficiency, dimensionless
P_F = power required at fan shaft, kW
DL = drive loss, dimensionless

Almost all the energy required to generate airflow and static pressure is ultimately dissipated as heat in the building and HVAC system; a small portion is discharged with any exhaust air. Generally, it is assumed that all the heat is released at the fan rather than dispersed to the remainder of the system. The portion of fan heat released to the airstream depends on the location of the fan motor and drive: if they are within the airstream, all the energy input to the fan motor is released to the airstream. If the fan motor and drive are outdoor the airstream, the energy is split between the airstream and the room housing the motor and drive. Therefore, the following equations may be used to calculate heat generated by fans and motors:

If motor and drive are **outside** the airstream,

$$q_{fs} = P_F$$

$$q_{fr} = (P_M - P_F)$$

If motor and drive are **inside** the airstream,

$$q_{fs} = P_M$$

$$q_{fr} = 0.0$$

where

P_F = power required at fan shaft, kW
P_M = power required at input to motor, kW
q_{fs} = heat release to airstream, kW
q_{fr} = heat release to room housing motor and drive, kW

Supply airstream temperature rise may be determined from psychrometric formulas or Equation (8).

Variable- or adjustable-frequency drives (VFDs or AFDs) often drive fan motors in VAV air-handling units. These devices release heat to the surrounding space. Refer to manufacturers' data for heat released or efficiencies. The disposition of heat released is determined by the drive's location: in the conditioned space, in the return air path, or in a nonconditioned equipment room. These drives, and other electronic equipment such as building control, data processing, and communications devices, are temperature sensitive, so the rooms in which they are housed require cooling, frequently year round.

Duct Surface Heat Transfer

Heat transfer across the duct surface is one mechanism for energy transfer to or from air inside a duct. It involves conduction through the duct wall and insulation, convection at inner and outer surfaces, and radiation between the duct and its surroundings. Chapter 4 presents a rigorous analysis of duct heat loss and gain, and Chapter 23 addresses application of analysis to insulated duct systems.

The effect of duct heat loss or gain depends on the duct routing, duct insulation, and its surrounding environment. Consider the following conditions:

- For duct run within the area cooled or heated by air in the duct, heat transfer from the space to the duct has no effect on heating or cooling load, but beware of the potential for condensation on cold ducts.
- For duct run through unconditioned spaces or outdoors, heat transfer adds to the cooling or heating load for the air transport system but not for the conditioned space.
- For duct run through conditioned space not served by the duct, heat transfer affects the conditioned space as well as the air transport system serving the duct.
- For an extensive duct system, heat transfer reduces the effective supply air differential temperature, requiring adjustment through air balancing to increase airflow to extremities of the distribution system.

Duct Leakage

Air leakage from supply ducts can considerably affect HVAC system energy use. Leakage reduces cooling and/or dehumidifying capacity for the conditioned space, and must be offset by increased airflow (sometimes reduced supply air temperatures), unless leaked air enters the conditioned space directly. Supply air leakage into a ceiling return plenum or leakage from unconditioned spaces into return ducts also affects return air temperature and/or humidity.

Licensed for single user. © 2021, ASHRAE, Inc.

Determining leakage from a duct system is complex because of the variables in paths, fabrication, and installation methods. Refer to Chapter 21 and publications from the Sheet Metal and Air Conditioning Contractors' National Association (SMACNA) for methods of determining leakage. In general, good-quality ducts and post-installation duct sealing provide highly cost-effective energy savings, with improved thermal comfort and delivery of ventilation air.

Ceiling Return Air Plenum Temperatures

The space above a ceiling, when used as a return air path, is a ceiling return air plenum, or simply a **return plenum**. Unlike a traditional ducted return, the plenum may have multiple heat sources in the air path. These heat sources may be radiant and convective loads from lighting and transformers; conduction loads from adjacent walls, roofs, or glazing; or duct and piping systems within the plenum.

As heat from these sources is picked up by the unducted return air, the temperature differential between the ceiling cavity and conditioned space is small. Most return plenum temperatures do not rise more than 0.6 to 1.7 K above space temperature, thus generating only a relatively small thermal gradient for heat transfer through plenum surfaces, except to the outdoors. This yields a relatively large-percentage reduction in space cooling load by shifting plenum loads to the system. Another reason plenum temperatures do not rise more is leakage into the plenum from supply air ducts, and, if exposed to the roof, increasing levels of insulation.

Where the ceiling space is used as a return air plenum, energy balance requires that heat picked up from the lights into the return air (1) become part of the cooling load to the return air (represented by a temperature rise of return air as it passes through the ceiling space), (2) be partially transferred back into the conditioned space through the ceiling material below, and/or (3) be partially lost from the space through floor surfaces above the plenum. If the plenum has one or more exterior surfaces, heat gains through them must be considered; if adjacent to spaces with different indoor temperatures, partition loads must be considered, too. In a multistory building, the conditioned space frequently gains heat through its floor from a similar plenum below, offsetting the floor loss. The radiant component of heat leaving the ceiling or floor surface of a plenum is normally so small, because of relatively small temperature differences, that all such heat transfer is considered convective for calculation purposes (Rock and Wolfe 1997).

Figure 15 shows a schematic of a typical return air plenum. The following equations, using the heat flow directions shown in Figure 15, represent the heat balance of a return air plenum design for a typical interior room in a multifloor building:

$$q_1 = U_c A_c (t_p - t_r) \tag{47}$$

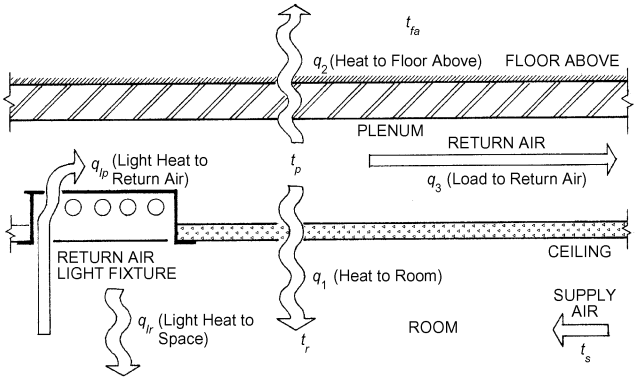

Fig. 15 Schematic Diagram of Typical Return Air Plenum

$$q_2 = U_f A_f (t_p - t_{fa}) \tag{48}$$

$$q_3 = 1.1 Q (t_p - t_r) \tag{49}$$

$$q_{lp} - q_2 - q_1 - q_3 = 0 \tag{50}$$

$$Q = \frac{q_r + q_1}{1.23(t_r - t_s)} \tag{51}$$

where

q_1 = heat gain to space from plenum through ceiling, kW
q_2 = heat loss from plenum through floor above, kW
q_3 = heat gain "pickup" by return air, kW
Q = return airflow, L/s
q_{lp} = light heat gain to plenum via return air, kW
q_{lr} = light heat gain to space, kW
q_f = heat gain from plenum below, through floor, kW
q_w = heat gain from exterior wall, kW
q_r = space cooling load, including appropriate treatment of q_{lr}, q_f, and/or q_w, kW
t_p = plenum air temperature, °C
t_r = space air temperature, °C
t_{fa} = space air temperature of floor above, °C
t_s = supply air temperature, °C

By substituting Equations (47), (48), (49), and (51) into heat balance Equation (50), t_p can be found as the resultant return air temperature or plenum temperature. The results, although rigorous and best solved by computer, are important in determining the cooling load, which affects equipment size selection, future energy consumption, and other factors.

Equations (47) to (51) are simplified to illustrate the heat balance relationship. Heat gain into a return air plenum is not limited to heat from lights. Exterior walls directly exposed to the ceiling space can transfer heat directly to or from return air. For single-story buildings or the top floor of a multistory building, roof heat gain or loss enters or leaves the ceiling plenum rather than the conditioned space directly. The supply air quantity calculated by Equation (51) is only for the conditioned space under consideration, and is assumed to equal the return air quantity.

The amount of airflow through a return plenum above a conditioned space may not be limited to that supplied into the space; it will, however, have no noticeable effect on plenum temperature if the surplus comes from an adjacent plenum operating under similar conditions. Where special conditions exist, Equations (47) to (51) must be modified appropriately. Finally, although the building's thermal storage has some effect, the amount of heat entering the return air is small and may be considered as convective for calculation purposes.

Ceiling Plenums with Ducted Returns

Compared to those in unducted plenum returns, temperatures in ceiling plenums that have well-sealed return or exhaust air ducts float considerably. In cooling mode, heat from lights and other equipment raises the ceiling plenum's temperature considerably. Solar heat gain through a poorly insulated roof can drive the ceiling plenum temperature to extreme levels, so much so that heat gains to uninsulated supply air ducts in the plenum can dramatically decrease available cooling capacity to the rooms below. In cold weather, much heat is lost from warm supply ducts. Thus, insulating supply air ducts and sealing them well to minimize air leaks are highly desirable, if not essential. Appropriately insulating roofs and plenums' exterior walls and minimizing infiltration are also key to lowering total building loads and improving HVAC system performance.

Underfloor Air Distribution Systems

Room cooling loads determined by methods in this chapter cannot model two distinguishing aspects of the thermal performance of underfloor air distribution (UFAD) systems under cooling operation:

- Room air stratification: UFAD systems supply cool air at the floor and extract warmer air at the ceiling, thus creating vertical thermal stratification. Cooling load models assume a well-mixed uniform space temperature.
- Underfloor air supply plenums: cool supply air flowing through the underfloor plenum is exposed to heat gain from both the concrete slab (conducted from the warm return air on the adjacent floor below in a multistory building) and the raised floor panels (conducted from the warmer room above).

Extensive simulation and experimental research led to the development of a whole-building energy simulation program capable of modeling energy performance and load calculations for UFAD systems (Bauman et al. 2007; Webster et al. 2008). Previously, it was thought that cooling loads for UFAD and overhead (OH) mixing systems were nearly identical. However, energy modeling studies show that the UFAD cooling load is generally higher than that calculated in the same building for a well-mixed system (Schiavon et al. 2010a). The difference is primarily caused by the thermal storage effect of the lower-mass raised-floor panels compared to the greater mass of a structural floor slab. Schiavon et al. (2010b) showed that the presence of the raised floor reduces the slab's ability to store heat, thereby producing higher peak cooling loads for a raised-floor system than for one without a raised floor. A second contributing factor is that the raised-floor surface above the underfloor plenum tends to be cooler (except when illuminated by the sun) than most other room surfaces, producing a room surface temperature distribution resembling a chilled radiant floor system, which has a different peak cooling load than an all-air system (Feng et al. 2012). The precise magnitude of difference in design cooling loads between OH and UFAD systems is still under investigation, but mainly depends on zone orientation and floor level, and possibly the effects of furniture. Methods for determining UFAD cooling loads will be updated as additional research results become available. For more information about simplified approaches to UFAD cooling load calculations, see the ASHRAE *Underfloor Air Distribution (UFAD) Design Guide* (ASHRAE 2013), Bauman et al. (2010), and Schiavon et al. (2010c).

Plenums in Load Calculations

Currently, most designers include ceiling and floor plenums within neighboring occupied spaces when thermally zoning a building. However, temperatures in these plenums, and the way that they behave, are significantly different from those of occupied spaces. Thus, they should be defined as a separate thermal zone. Most hand and computer-based load calculation routines, though, currently do not allow floating air temperatures or humidities; assuming a constant air temperature in plenums, attics, and other unconditioned spaces is a poor, but often necessary, assumption. The heat balance method does allow floating space conditions, and when fully implemented in design load software, should allow more accurate modeling of plenums and other complex spaces.

8.4 CENTRAL PLANT

Piping

Losses must be considered for piping systems that transport heat. For water or hydronic piping systems, heat is transferred through the piping and insulation (see Chapter 23 for ways to determine this transfer). However, distribution of this transferred heat depends on the fluid in the pipe and the surrounding environment.

Consider a heating hot-water pipe. If the pipe serves a room heater and is routed through the heated space, any heat loss from the pipe adds heat to the room. Heat transfer to the heated space and heat loss from the piping system is null. If the piping is exposed to ambient conditions en route to the heater, the loss must be considered when selecting the heating equipment; if the pipe is routed through a space requiring cooling, heat loss from the piping also becomes a load on the cooling system.

In summary, the designer must evaluate both the magnitude of the pipe heat transfer and the routing of the piping.

Pumps

Calculating heat gain from pumps is addressed in the section on Electric Motors. For pumps serving hydronic systems, disposition of heat from the pumps depends on the service. For chilled-water systems, energy applied to the fluid to generate flow and pressure becomes a chiller load. For condenser water pumps, pumping energy must be rejected through the cooling tower. The magnitude of pumping energy relative to cooling load is generally small.

9. EXAMPLE COOLING AND HEATING LOAD CALCULATIONS

To illustrate the cooling and heating load calculation procedures discussed in this chapter, an example problem has been developed based on the ASHRAE headquarters building located in Atlanta, Georgia. This example is a two-story office building of approximately 3250 m^2, including a variety of common office functions and occupancies. In addition to demonstrating calculation procedures, a hypothetical design/construction process is discussed to illustrate (1) application of load calculations and (2) the need to develop reasonable assumptions when specific data are not yet available, as often occurs in everyday design processes.

Table 26 summarizes RTS load calculation procedures.

9.1 SINGLE-ROOM EXAMPLE

Calculate the peak heating and cooling loads for the office room shown in Figure 16, for Atlanta, Georgia. The room is on the second floor of a two-story building and has two vertical exterior exposures, with a flat roof above.

Table 26 Summary of RTS Load Calculation Procedures

Equation	Equation No. in Chapter
External Heat Gain	
Sol-Air Temperature	
$t_e = t_o + \frac{\alpha E_t}{h_o} - \frac{\varepsilon \Delta R}{h_o}$	(29)
where	
t_e = sol-air temperature, °C	
t_o = outdoor air temperature, °C	
a = absorptance of surface for solar radiation	
E_t = total solar radiation incident on surface, W/m^2	
h_o = coefficient of heat transfer by long-wave radiation and convection at outer surface, W/(m^2·K)	
ε = hemispherical emittance of surface	
ΔR = difference between long-wave radiation incident on surface from sky and surroundings and radiation emitted by blackbody at outdoor air temperature, W/m^2; 20 for horizontal surfaces; 0 for vertical surfaces	
Wall and Roof Transmission	
$q_\theta = c_0 q_{i,\theta} + c_1 q_{i,\theta\text{-}1} + c_2 q_{i,\theta\text{-}2} + \cdots + c_{23} q_{i,\theta\text{-}23}$	(31)
$q_{i,\theta\text{-}n} = UA(t_{e,\theta\text{-}n} - t_{rc})$	(30)
where	
q_θ = hourly conductive heat gain for surface, W	
$q_{i,\theta}$ = heat input for current hour	
$q_{i,\theta\text{-}n}$ = conductive heat input for surface n hours ago, W	
c_0, c_1, etc. = conduction time factors	
U = overall heat transfer coefficient for surface, W/(m^2·K)	
A = surface area, m^2	
Fenestration Transmission	
$q_c = UA(T_{out} - T_{in})$	(14)
where	
q = fenestration transmission heat gain, W	
U = overall U-factor, including frame and mounting orientation from Table 4 of Chapter 15, W/(m^2·K)	
A = window area, m^2	
T_{in} = indoor temperature, °C	
T_{out} = outdoor temperature, °C	
Fenestration Solar	
T_{out} = outdoor temperature, °C	
$q_b = AE_{t,b}\,\mathrm{SHGC}(\theta)\mathrm{IAC}(\theta,\Omega)$	(12)
$q_d = A(E_{t,d} + E_{t,r})\langle \mathrm{SHGC} \rangle_D \,\mathrm{IAC}_D$	(13)
where	
q_b = beam solar heat gain, W	
q_d = diffuse solar heat gain, W	
A = window area, m^2	
$E_{t,b}$, $E_{t,d}$, and $E_{t,r}$ = beam, sky diffuse, and ground-reflected diffuse irradiance, calculated using equations in Chapter 14	
SHGC(θ) = beam solar heat gain coefficient as a function of incident angle θ; may be interpolated between values in Table 10 of Chapter 15	
IAC(θ.Ω) = indoor solar attenuation coefficient for beam solar heat gain coefficient; = 1.0 if no indoor shading device. IAC(θ.Ω) is a function of shade type and, depending on type, may also be a function of beam solar angle of incidence θ and shade geometry	
IAC_D = indoor solar attenuation coefficient for diffuse solar heat gain coefficient; = 1.0 if not indoor shading device. IAC_D is a function of shade type and, depending on type, may also be a function of shade geometry	
Partitions, Ceilings, Floors Transmission	
$q = UA(t_b - t_i)$	(32)
where	
q = heat transfer rate, W	
U = coefficient of overall heat transfer between adjacent and conditioned space, W/(m^2·K)	
A = area of separating section concerned, m^2	
t_b = average air temperature in adjacent space, °C	
t_i = air temperature in conditioned space, °C	
Internal Heat Gain	
Occupants	
$q_s = q_{s,per} N$	
$q_l = q_{l,per} N$	
where	
q_s = occupant sensible heat gain, W	
q_l = occupant latent heat gain, W	
$q_{l,per}$ = latent heat gain per person, W/person; see Table 1	
N = number of occupants	
Lighting	
$q_{el} = WF_{ul}F_{sa}$	(1)
where	
q_{el} = heat gain, W	
W = total light wattage, W	
F_{ul} = lighting use factor	
F_{sa} = lighting special allowance factor	
Electric Motors	
$q_{em} = (P/E_M)F_{UM}F_{LM}$	(2)
where	
q_{em} = heat equivalent of equipment operation, W	
P = motor power rating, W	
E_M = motor efficiency, decimal fraction <1.0	
F_{UM} = motor use factor, 1.0 or decimal fraction <1.0	
F_{LM} = motor load factor, 1.0 or decimal fraction <1.0	
Hooded Cooking Appliances	
$q_s = q_{input} F_U F_R$	
where	
q_s = sensible heat gain, W	
q_{input} = nameplate or rated energy input, W	
F_U = usage factor; see Tables 5B, 5C, 5D	
F_R = radiation factor; see Tables 5B, 5C, 5D	
For other appliances and equipment, find q_s for	
Unhooded cooking appliances: Table 5A	
Other kitchen equipment: Table 5E	
Hospital and laboratory equipment: Tables 6 and 7	
Computers, printers, scanners, etc.: Tables 8 and 9	
Miscellaneous office equipment: Table 10	
Find q_l for	
Unhooded cooking appliances: Table 5A	
Other kitchen equipment: Table 5E	
Ventilation and Infiltration Air Heat Gain	
$q_s = 1.23 Q_s \Delta t$	(9)
$q_l = 1.20 \times 2500 Q_s \Delta W = 3010 Q_s \Delta W$	(10)
where	
q_s = sensible heat gain due to infiltration, W

Table 26 Summary of RTS Load Calculation Procedures (*Concluded*)

Equation	Equation No. in Chapter

q_l = latent heat gain due to infiltration, W
Q_s = infiltration airflow at standard air conditions, m^3/s
t_o = outdoor air temperature, °C
t_i = indoor air temperature, °C
W_o = outdoor air humidity ratio, kg/kg
W_i = indoor air humidity ratio, kg/kg
1.23 = air sensible heat factor at standard air conditions, $W/(m^3 \cdot s)$
3010 = air latent heat factor at standard air conditions, $W/(m^3 \cdot s)$

Instantaneous Room Cooling Load

$$Q_s = \Sigma Q_{i,r} + \Sigma Q_{i,c}$$

$$Q_l = \Sigma q_{i,l}$$

where

Q_s = room sensible cooling load, W
$Q_{i,r}$ = radiant portion of sensible cooling load for current hour, resulting from heat gain element i, W
$Q_{i,c}$ = convective portion of sensible cooling load, resulting from heat gain element i, W
Q_l = room latent cooling load, W
$q_{i,l}$ = latent heat gain for heat gain element i, W

Radiant Portion of Sensible Cooling Load

$$Q_{i,r} = Q_{r,\theta}$$

$$Q_{r,\theta} = r_0 q_{r,\theta} + r_1 q_{r,\theta-1} + r_2 q_{r,\theta-2} + r_3 q_{r,\theta-3} + \cdots + r_{23} q_{r,\theta-23} \quad (33)$$

where

$Q_{r,\theta}$ = radiant cooling load Q_r for current hour θ, W
$q_{r,\theta}$ = radiant heat gain for current hour, W
$q_{r,\theta-n}$ = radiant heat gain n hours ago, W
r_0, r_1, etc. = radiant time factors; see Table 19 for radiant time factors for nonsolar heat gains: wall, roof, partition, ceiling, floor, fenestration transmission heat gains, and occupant, lighting, motor, appliance heat gain. Also used for fenestration diffuse solar heat gain; see Table 20 for radiant time factors for fenestration beam solar heat gain.

Equation	Equation No. in Chapter

$$q_{r,\theta} = q_{i,s} F_r$$

where

$q_{i,s}$ = sensible heat gain from heat gain element i, W
F_r = fraction of heat gain that is radiant.

Lighting: see Table 3

Convective Portion of Sensible Cooling Load

$$Q_{i,c} = q_{i,c}$$

where $q_{i,c}$ is convective portion of heat gain from heat gain element i, W.

$$q_{i,c} = q_{i,s}(1 - F_r)$$

where

$q_{i,s}$ = sensible heat gain from heat gain element i, W
F_r = fraction of heat gain that is radiant; see row for radiant portion for sources of radiant fraction data for individual heat gain elements

Room Characteristics

Area: 12 m^2.

Floor: Carpeted 127 mm concrete slab on metal deck above a conditioned space.

Roof: Flat metal deck topped with rigid closed-cell polyisocyanurate foam core insulation (R = 5.3), and light-colored membrane roofing. Space above 2.75 m suspended acoustical tile ceiling is used as a return air plenum. Assume 30% of cooling load from the roof is directly absorbed in the return airstream without becoming room load. Use roof U = 0.18 $W/(m^2 \cdot K)$.

Spandrel wall: Spandrel bronze-tinted glass, opaque, backed with air space, rigid mineral fiber insulation (R = 0.88), mineral fiber batt insulation (R = 2.3), and 16 mm gypsum wall board. Use spandrel wall U = 0.44 $W/(m^2/K)$.

Brick wall: Light-brown-colored face brick (102 mm), low-mass concrete block (152 mm), rigid continuous insulation (R = 0.88), mineral fiber batt insulation (R = 2.3), and gypsum wall board (16 mm). Use brick wall U = 0.44 $W/(m^2 \cdot K)$.

Windows: Double glazed, 6 mm bronze-tinted outdoor pane, 13 mm air space and 6 mm clear indoor pane with light-colored interior miniblinds. Window normal solar heat gain coefficient (SHGC) = 0.49. Windows are nonoperable and mounted in aluminum frames with thermal breaks having overall combined U = 3.18 $W/(m^2 \cdot K)$ (based on Type 5d from Tables 4 and 10 of Chapter 15). Indoor attenuation coefficients (IACs) for indoor miniblinds are based on light venetian blinds (assumed louver reflectance = 0.8 and louvers positioned at 45° angle) with heat-absorbing double glazing (Type 5d from Table 14B of Chapter 15), IAC(0) = 0.74, IAC(60) = 0.65, IAD(diff) = 0.79, and radiant fraction = 0.54. Each window is 1.91 m wide by 1.95 m tall for an area per window = 3.72 m^2.

South exposure:	Orientation	= 30° east of true south
	Window area	= 3.72 m^2
	Spandrel wall area	= 5.57 m^2
	Brick wall area	= 5.57 m^2
West exposure:	Orientation	= 60° west of south
	Window area	= 3.72 m^2
	Spandrel wall area	= 5.57 m^2
	Brick wall area	= 3.72 m^2

Occupancy: 1 person from 8:00 AM to 5:00 PM.

Lighting: One 4-lamp pendant fluorescent 2440 mm type. The fixture has four 32 W T-8 lamps plus electronic ballasts (special allowance factor 0.85 per manufacturer's data), for a total of 110 W for the room. Operation is from 7:00 AM to 7:00 PM. Assume 0% of cooling load from lighting is directly absorbed in the return airstream without becoming room load, per Table 3.

Equipment: One computer and a personal printer are used, for which an allowance of 10.76 W/m^2 is to be accommodated by the cooling system, for a total of 130 W for the room. Operation is from 8:00 AM to 5:00 PM.

Infiltration: For purposes of this example, assume the building is maintained under positive pressure during peak cooling conditions and therefore has no infiltration. Assume that infiltration during peak heating conditions is equivalent to one air change per hour.

Weather data: Per Chapter 14, for Atlanta, Georgia, latitude = 33.64, longitude = 84.43, elevation = 313 m above sea level, 99.6% heating design dry-bulb temperature = –5.6°C. For cooling load calculations, use 5% dry-bulb/coincident wet-bulb monthly design day profile calculated per Chapter 14. See Table 27 for temperature profiles used in these examples.

Indoor design conditions: 22.2°C for heating; 23.9°C with 50% rh for cooling.

Cooling Loads Using RTS Method

Traditionally, simplified cooling load calculation methods have estimated the total cooling load at a particular design condition by independently calculating and then summing the load from each component (walls, windows, people, lights, etc). Although the actual heat transfer processes for each component do affect each other, this simplification is appropriate for design load calculations and useful to the designer in understanding the relative contribution of each component to the total cooling load.

Cooling loads are calculated with the RTS method on a component basis similar to previous methods. The following example parts illustrate cooling load calculations for individual components of this single room for a particular hour and month. Equations used are summarized in Table 26.

Part 1. Internal cooling load using radiant time series. Calculate the cooling load from lighting at 3:00 PM for the previously described office.

Solution: First calculate the 24 h heat gain profile for lighting, then split those heat gains into radiant and convective portions, apply the appropriate RTS to the radiant portion, and sum the convective and radiant cooling load components to determine total cooling load at the designated time. Using Equation (1), the lighting heat gain profile, based on the occupancy schedule indicated is

$q_1 = (110\text{ W})(0\%) = 0$ $q_{13} = (110\text{ W})(100\%) = 110$
$q_2 = (110\text{ W})(0\%) = 0$ $q_{14} = (110\text{ W})(100\%) = 110$
$q_3 = (110\text{ W})(0\%) = 0$ $q_{15} = (110\text{ W})(100\%) = 110$
$q_4 = (110\text{ W})(0\%) = 0$ $q_{16} = (110\text{ W})(100\%) = 110$
$q_5 = (110\text{ W})(0\%) = 0$ $q_{17} = (110\text{ W})(100\%) = 110$
$q_6 = (110\text{ W})(0\%) = 0$ $q_{18} = (110\text{ W})(100\%) = 110$
$q_7 = (110\text{ W})(100\%) = 110$ $q_{19} = (110\text{ W})(0\%) = 0$
$q_8 = (110\text{ W})(100\%) = 110$ $q_{20} = (110\text{ W})(0\%) = 0$
$q_9 = (110\text{ W})(100\%) = 110$ $q_{21} = (110\text{ W})(0\%) = 0$
$q_{10} = (110\text{ W})(100\%) = 110$ $q_{22} = (110\text{ W})(0\%) = 0$
$q_{11} = (110\text{ W})(100\%) = 110$ $q_{23} = (110\text{ W})(0\%) = 0$
$q_{12} = (110\text{ W})(100\%) = 110$ $q_{24} = (110\text{ W})(0\%) = 0$

The convective portion is simply the lighting heat gain for the hour being calculated times the convective fraction for non-in-ceiling fluorescent luminaire (pendant), from Table 3:

$$Q_{c,15} = (110)(43\%) = 47.3\text{ W}$$

The radiant portion of the cooling load is calculated using lighting heat gains for the current hour and past 23 h, the radiant fraction from Table 3 (57%), and radiant time series from Table 19, in accordance with Equation (33). From Table 19, select the RTS for medium-weight construction, assuming 50% glass and carpeted floors as representative of the described construction. Thus, the radiant cooling load for lighting is

$$\begin{aligned} Q_{r,15} &= r_0(0.48)q_{15} + r_1(0.48)q_{14} + r_2(0.48)q_{13} + r_3(0.48)q_{12} + \cdots \\ &\quad + r_{23}(0.48)q_{16} \\ &= (0.49)(0.57)(110) + (0.17)(0.57)(110) + (0.09)(0.57)(110) \\ &\quad + (0.05)(0.57)(110) + (0.03)(0.57)(110) + (0.02)(0.57)(110) \\ &\quad + (0.02)(0.57)(110) + (0.01)(0.57)(110) + (0.01)(0.57)(110) \\ &\quad + (0.01)(0.57)(0) + (0.01)(0.57)(0) + (0.01)(0.57)(0) \\ &\quad + (0.01)(0.57)(0) + (0.01)(0.57)(0) + (0.01)(0.57)(0) \\ &\quad + (0.01)(0.57)(0) + (0.01)(0.57)(0) + (0.01)(0.57)(0) \end{aligned}$$

+ (0.01)(0.57)(0) + (0.01)(0.57)(0) + (0.00)(0.57)(0)
+ (0.00)(0.57)(440) + (0.00)(0.57)(440)
+ (0.00)(0.57)(440) = 55.77 W

The total lighting cooling load at the designated hour is thus

$$Q_{light} = Q_{c,15} + Q_{r,15} = 47.3 + 55.7 = 103 \text{ W}$$

See Table 28 for the office's lighting usage, heat gain, and cooling load profiles.

Part 2. Wall cooling load using sol-air temperature, conduction time series and radiant time series. Calculate the cooling load contribution from the spandrel wall section facing 60° west of south at 3:00 PM local standard time in July for the previously described office.

Solution: Determine the wall cooling load by calculating (1) sol-air temperatures at the exterior surface, (2) heat input based on sol-air temperature, (3) delayed heat gain through the mass of the wall to the interior surface using conduction time series, and (4) delayed space cooling load from heat gain using radiant time series.

First, calculate the sol-air temperature at 3:00 PM local standard time (LST) (4:00 PM daylight saving time) on July 21 for a vertical, dark-colored wall surface, facing 60° west of south, located in Atlanta, Georgia (latitude = 33.64, longitude = 84.43), solar clear sky optical depth for beam irradiance τ_b ("taub") = 0.515 and τ_d ("taud") for diffuse irradiance = 2.066 from monthly Atlanta weather data for July (Table 1 in Chapter 14). From Table 27, the calculated outdoor design temperature for that month and time is 33.3°C. The ground reflectivity is assumed $\rho_g = 0.2$.

Sol-air temperature is calculated using Equation (30). For the dark-colored wall, $\alpha/h_o = 0.053$, and for vertical surfaces, $\varepsilon\Delta R/h_o = 0$. The solar irradiance E_t on the wall must be determined using the equations in Chapter 14:

Solar Angles:

ψ = southwest orientation = +60°
Σ = surface tilt from horizontal (where horizontal = 0°) = 90° for vertical wall surface
3:00 PM LST = hour 15

Calculate solar altitude, solar azimuth, surface solar azimuth, and incident angle as follows:

From Table 2 in Chapter 14, solar position data and constants for July 21 are

ET = –6.4 min
δ = 20.4°
E_o = 1324 W/m^2

Local standard meridian (LSM) for Eastern Time Zone = 75°.

Apparent solar time AST

$$\begin{aligned} \text{AST} &= \text{LST} + \text{ET}/60 + (\text{LSM} - \text{LON})/15 \\ &= 15 + (-6.4/60) + [(75 - 84.43)/15] \\ &= 14.2647 \end{aligned}$$

Hour angle H, degrees

$$\begin{aligned} H &= 15(\text{AST} - 12) \\ &= 15(14.2647 - 12) \\ &= 33.97° \end{aligned}$$

Solar altitude β

$$\begin{aligned} \sin\beta &= \cos L \cos\delta \cos H + \sin L \sin\delta \\ &= \cos(33.64)\cos(20.4)\cos(33.97) + \sin(33.64)\sin(20.4) \\ &= 0.841 \\ \beta &= \sin^{-1}(0.841) = 57.2° \end{aligned}$$

Solar azimuth ϕ

$$\begin{aligned} \cos\phi &= (\sin\beta \sin L - \sin\delta)/(\cos\beta \cos L) \\ &= [(\sin(57.2)\sin(33.64) - \sin(20.4)]/[\cos(57.2)\cos(33.64)] \\ &= 0.258 \\ \phi &= \cos^{-1}(0.253) = 75.05° \end{aligned}$$

Surface-solar azimuth γ

$$\begin{aligned} \gamma &= \phi - \psi \\ &= 75.05 - 60 \\ &= 15.05° \end{aligned}$$

Incident angle θ

$$\begin{aligned} \cos\theta &= \cos\beta \cos g \sin\Sigma + \sin\beta \cos\Sigma \\ &= \cos(57.2)\cos(15.05)\sin(90) + \sin(57.2)\cos(90) \end{aligned}$$

$= 0.523$

$\theta = \cos^{-1}(0.523) = 58.45°$

Beam normal irradiance E_b

$E_b = E_o \exp(-\tau_b m^{ab})$

m = relative air mass

$= 1/[\sin\beta + 0.50572(6.07995 + \beta)^{-1.6364}]$, β expressed in degrees

$= 1.18905$

ab = beam air mass exponent

$= 1.454 - 0.406\tau_b - 0.268\tau_d + 0.021\tau_b\tau_d$

$= 0.713566$

$E_b = 1324 \exp[-0.556(1.8905^{0.7055705})]$

$= 805$ W/m^2

Surface beam irradiance $E_{t,b}$

$E_{t,b} = E_b \cos\theta$

$= (805)\cos(58.5)$

$= 421$ W/m^2

Ratio Y of sky diffuse radiation on vertical surface to sky diffuse radiation on horizontal surface

$Y = 0.55 + 0.437\cos\theta + 0.313\cos^2\theta$

$= 0.55 + 0.437\cos(58.45) + 0.313\cos^2(58.45)$

$= 0.8644$

Diffuse irradiance E_d – Horizontal surfaces

$E_d = E_o \exp(-\tau_d m^{ad})$

ad = diffuse air mass exponent

$= 0.507 + 0.205\tau_b - 0.080\tau_d - 0.190\tau_b\tau_d$

$= 0.245137$

$E_d = E_o \exp(-\tau_d m^{ad})$

$= 1324 \exp(-2.202(1.8905^{0.2369528})]$

$= 133$ W/m^2

Diffuse irradiance E_d – Vertical surfaces

$E_{t,d} = E_d Y$

$= (133)(0.864)$

$= 115$ W/m^2

Ground reflected irradiance $E_{t,r}$

$E_{t,r} = (E_b \sin\beta + E_d)\rho_g(1 - \cos\Sigma)/2$

$= [805\sin(57.2) + 133](0.2)[1 - \cos(90)]/2$

$= 81$ W/m^2

Total surface irradiance E_t

$E_t = E_D + E_d + E_r$

$= 421 + 115 + 81$

$= 617$ W/m^2

Sol-air temperature [from Equation (29)]:

$T_e = t_o + \alpha E_t/h_o - \varepsilon\Delta R/h_o$

$= 33.3 + (0.053)(617) - 0$

$= 66.0°$C

This procedure is used to calculate the sol-air temperatures for each hour on each surface. Because of the tedious solar angle and intensity calculations, using a simple computer spreadsheet or other computer software can reduce the effort involved. A spreadsheet was used to calculate a 24 h sol-air temperature profile for the data of this example. See Table 29A for the solar angle and intensity calculations and Table 29B for the sol-air temperatures for this wall surface and orientation.

Conductive heat gain is calculated using Equations (30) and (31). First, calculate the 24 h heat input profile using Equation (30) and the sol-air temperatures for a southwest-facing wall with dark exterior color:

$q_{i,1} = (0.44)(5.57)(23.2 - 23.9) = -1$ W

$q_{i,2} = (0.44)(5.57)(22.8 - 23.9) = -3$

$q_{i,3} = (0.44)(5.57)(22.4 - 23.9) = -4$

$q_{i,4} = (0.44)(5.57)(22.1 - 23.9) = -4$

$q_{i,5} = (0.44)(5.57)(21.9 - 23.9) = -5$

$q_{i,6} = (0.44)(5.57)(22.6 - 23.9) = -3$

$q_{i,7} = (0.44)(5.57)(25.2 - 23.9) = 3$

$q_{i,8} = (0.44)(5.57)(29.0 - 23.9) = 12$

$q_{i,9} = (0.44)(5.57)(32.7 - 23.9) = 21$

$q_{i,10} = (0.44)(5.57)(35.9 - 23.9) = 29$

$q_{i,11} = (0.44)(5.57)(38.6 - 23.9) = 36$

$q_{i,12} = (0.44)(5.57)(40.8 - 23.9) = 41$

$q_{i,13} = (0.44)(5.57)(50.2 - 23.9) = 64$

$q_{i,14} = (0.44)(5.57)(59.8 - 23.9) = 87$

$q_{i,15} = (0.44)(5.57)(65.9 - 23.9) = 102$

$q_{i,16} = (0.44)(5.57)(67.6 - 23.9) = 107$

$q_{i,17} = (0.44)(5.57)(64.3 - 23.9) = 98$

$q_{i,18} = (0.44)(5.57)(55.4 - 23.9) = 77$

$q_{i,19} = (0.44)(5.57)(39.5 - 23.9) = 38$

$q_{i,20} = (0.44)(5.57)(27.6 - 23.9) = 9$

$q_{i,21} = (0.44)(5.57)(26.6 - 23.9) = 6$

$q_{i,22} = (0.44)(5.57)(25.6 - 23.9) = 4$

$q_{i,23} = (0.44)(5.57)(24.7 - 23.9) = 2$

$q_{i,24} = (0.44)(5.57)(23.9 - 23.9) = 0$

Next, calculate wall heat gain using conduction time series. The preceding heat input profile is used with conduction time series to calculate the wall heat gain. From Table 16, the most similar wall construction is wall number 1. This is a spandrel glass wall that has similar mass and thermal capacity. Using Equation (31), the conduction time factors for wall 1 can be used in conjunction with the 24 h heat input profile to determine the wall heat gain at 3:00 PM LST:

$q_{15} = c_0 q_{i,15} + c_1 q_{i,14} + c_2 q_{i,13} + c_3 q_{i,12} + \cdots + c_{23} q_{i,16}$

$= (0.18)(20) + (0.58)(20) + (0.20)(19) + (0.04)(17)$
$+ (0.00)(14) + (0.00)(10) + (0.00)(5) + (0.00)(0)$
$+ (0.00)(-5) + (0.00)(-7) + (0.00)(-7) + (0.00)(-7)$
$+ (0.00)(-6) + (0.00)(-5) + (0.00)(-4) + (0.00)(-2)$
$+ (0.00)(0) + (0.00)(2) + (0.00)(4) + (0.00)(7)$
$+ (0.00)(10) + (0.00)(14) + (0.00)(17) + (0.00)(19)$

$= 83.5$ W

Because of the tedious calculations involved, a spreadsheet is used to calculate the remainder of a 24 h heat gain profile indicated in Table 29B for the data of this example.

Finally, calculate wall cooling load using radiant time series. Total cooling load for the wall is calculated by summing the convective and radiant portions. The convective portion is simply the wall heat gain for the hour being calculated times the convective fraction for walls from Table 14 (54%):

$$Q_c = (83.5)(0.54) = 45 \text{ W}$$

The radiant portion of the cooling load is calculated using conductive heat gains for the current and past 23 h, the radiant fraction for walls from Table 14 (46%), and radiant time series from Table 19, in accordance with Equation (33). From Table 19, select the RTS for medium-weight construction, assuming 50% glass and carpeted floors as representative for the described construction. Use the wall heat gains from Table 29B for 24 h design conditions in July. Thus, the radiant cooling load for the wall at 3:00 PM is

$Q_{r,15} = r_0(0.46)q_{i,15} + r_1(0.46)\, q_{i,14} + r_2(0.46)\, q_{i,13} + r_3(0.46)\, q_{i,12}$
$+ \cdots + r_{23}(0.46)\, q_{i,16}$

$= (0.49)(0.46)(84) + (0.17)(0.46)(63) + (0.09)(0.46)(44)$
$+ (0.05)(0.46)(35) + (0.03)(0.46)(28) + (0.02)(0.46)(20)$
$+ (0.02)(0.46)(12) + (0.01)(0.46)(3) + (0.01)(0.46)(-2)$
$+ (0.01)(0.46)(-4) + (0.01)(0.46)(-4) + (0.01)(0.46)(-3)$
$+ (0.01)(0.46)(-2) + (0.01)(0.46)(-1) + (0.01)(0.46)(0)$
$+ (0.01)(0.46)(2) + (0.01)(0.46)(4) + (0.01)(0.46)(8)$
$+ (0.01)(0.46)(17) + (0.01)(0.46)(43) + (0.00)(0.46)(75)$
$+ (0.00)(0.46)(96) + (0.00)(0.46)(103) + (0.00)(0.46)(99)$

$= 27$ W

The total wall cooling load at the designated hour is thus

$$Q_{wall} = Q_c + Q_{r15} = 45 + 27 = 72 \text{ W}$$

Again, a simple computer spreadsheet or other software is necessary to reduce the effort involved. A spreadsheet was used with the heat gain profile to split the heat gain into convective and radiant portions, apply RTS to the radiant portion, and total the convective and radiant loads to determine a 24 h cooling load profile for this example, with results in Table 29B.

Part 3. Window cooling load using radiant time series. Calculate the cooling load contribution, with and without indoor shading (venetian blinds) for the window area facing 60° west of south at 3:00 PM in July for the conference room example.

24	0.0	23.9	23.9	23.9	0	0	2	1	1	0	6	7

Solution: First, calculate the 24 h heat gain profile for the window, then split those heat gains into radiant and convective portions, apply the appropriate RTS to the radiant portion, then sum the convective and radiant cooling load components to determine total window cooling load for the time. The window heat gain components are calculated using Equations (12) to (14). From Part 2, at hour 15 LST (3:00 PM):

$E_{t,b}$ = 421 W/m²
$E_{t,d}$ = 115 W/m²
E_r = 81 W/m²
θ = 58.45°

From Chapter 15, Table 10, for glass type 5d,

$$\text{SHGC}(\theta) = \text{SHGC}(58.45) = 0.3978 \text{ (interpolated)}$$

$$\langle \text{SHGC} \rangle_D = 0.41$$

From Chapter 15, Table 14B, for light-colored blinds (assumed louver reflectance = 0.8 and louvers positioned at 45° angle) on double-glazed, heat-absorbing windows (Type 5d from Table 13B of Chapter 15), IAC(0) = 0.74, IAC(60) = 0.65, IAC(diff) = 0.79, and radiant fraction = 0.54. Without blinds, IAC = 1.0. Therefore, window heat gain components for hour 15, without blinds, are

$$q_{b15} = AE_{t,b}\,\text{SHGC}(\theta)(\text{IAC}) = (3.72)(421)(0.3978)(1.00) = 623 \text{ W}$$

$$q_{d15} = A(E_{t,d} + E_r)\langle \text{SHGC} \rangle_D(\text{IAC}) = (3.72)(115 + 81)(0.41)(1.00)$$
$$= 299 \text{ W}$$

$$q_{c15} = UA(t_{out} - t_{in}) = (3.18)(3.72)(33.3 - 23.9) = 111 \text{ W}$$

This procedure is repeated to determine these values for a 24 h heat gain profile, shown in Table 30.

Total cooling load for the window is calculated by summing the convective and radiant portions. For windows with indoor shading (blinds, drapes, etc.), the direct beam, diffuse, and conductive heat gains may be summed and treated together in calculating cooling loads. However, in this example, the window does not have indoor shading, and the direct beam solar heat gain should be treated separately from the diffuse and conductive heat gains. The direct beam heat gain, without indoor shading, is treated as 100% radiant, and solar RTS factors from Table 20 are used to convert the beam heat gains to cooling loads. The diffuse and conductive heat gains can be totaled and split into radiant and convective portions according to Table 14, and nonsolar RTS factors from Table 19 are used to convert the radiant portion to cooling load.

The solar beam cooling load is calculated using heat gains for the current hour and past 23 h and radiant time series from Table 20, in accordance with Equation (38). From Table 20, select the solar RTS for medium-weight construction, assuming 50% glass and carpeted floors for this example. Using Table 30 values for direct solar heat gain, the radiant cooling load for the window direct beam solar component is

$$\begin{aligned} Q_{b,15} &= r_0 q_{b,15} + r_1 q_{b,14} + r_2 q_{b,13} + r_3 q_{b,12} + \cdots + r_{23} q_{b,14} \\ &= (0.54)(783) + (0.16)(362) + (0.08)(89) + (0.04)(0) \\ &\quad + (0.03)(0) + (0.02)(0) + (0.01)(0) + (0.01)(0) + (0.01)(0) \\ &\quad + (0.01)(0) + (0.01)(0) + (0.01)(0) + (0.01)(0) + (0.01)(0) \\ &\quad + (0.01)(0) + (0.01)(0) + (0.01)(0) + (0.01)(0) + (0.01)(0) \\ &\quad + (0.00)(0) + (0.00)(254) + (0.00)(610) + (0.00)(779) \\ &\quad + (0.00)(783) = 488 \text{ W} \end{aligned}$$

This process is repeated for other hours; results are listed in Table 31.

For diffuse and conductive heat gains, the radiant fraction according to Table 14 is 46%. The radiant portion is processed using nonsolar RTS coefficients from Table 19. The results are listed in Tables 30 and 31. For 3:00 PM, the diffuse and conductive cooling load is 380 W.

The total window cooling load at the designated hour is thus

$$Q_{window} = Q_b + Q_{diff+cond} = 488 + 380 = 868 \text{ W}$$

Again, a computer spreadsheet or other software is commonly used to reduce the effort involved in calculations. The spreadsheet shown in Table 30 is expanded in Table 31 to include splitting the heat gain into convective and radiant portions, applying RTS to the radiant portion, and totaling the convective and radiant loads to determine a 24 h cooling load profile for a window without indoor shading.

If the window has an indoor shading device, it is accounted for with the indoor attenuation coefficients (IAC), the radiant fraction, and the RTS type used. If a window has no indoor shading, 100% of the direct beam energy is assumed to be radiant and solar RTS factors are used. However, if an indoor shading device is present, the direct beam is assumed to be interrupted by the shading device, and a portion immediately becomes cooling load by convection. Also, the energy is assumed to be radiated to all surfaces of the room, therefore nonsolar RTS values are used to convert the radiant load into cooling load.

IAC values depend on several factors: (1) type of shading device, (2) position of shading device relative to window, (3) reflectivity of shading device, (4) angular adjustment of shading device, as well as (5) solar position relative to the shading device. These factors are discussed

in detail in Chapter 15. For this example with venetian blinds, the IAC for beam radiation is treated separately from the diffuse solar gain. The direct beam IAC must be adjusted based on the profile angle of the sun. At 3:00 PM in July, the profile angle of the sun relative to the window surface is 58°. Calculated using Equation (38) from Chapter 15, the beam IAC = 0.653. The diffuse IAC is 0.79. Thus, the window heat gains, with light-colored blinds, at 3:00 PM are

$$q_{b15} = AE_D \,\mathrm{SHGC}(\theta)(\mathrm{IACb}) = (3.72)(421)(0.3978)(0.653) = 406 \text{ W}$$

$$q_{d15} = A(E_d + E_r)\langle \mathrm{SHGC} \rangle_D (\mathrm{IACd}) = (3.72)(115 + 81)(0.41)(0.79) = 236 \text{ W}$$

$$q_{c15} = UA(t_{out} - t_{in}) = (3.18)(3.72)(33.3 - 23.9) = 111 \text{ W}$$

Because the same radiant fraction and nonsolar RTS are applied to all parts of the window heat gain when indoor shading is present, those loads can be totaled and the cooling load calculated after splitting the radiant portion for processing with nonsolar RTS. This is shown by the spreadsheet results in Table 32. The total window cooling load with venetian blinds at 3:00 PM = 636 W.

Part 4. Window cooling load using radiant time series for window with overhang shading. Calculate the cooling load contribution for the previous example with the addition of a 3 m overhang shading the window.

Solution: In Chapter 15, methods are described and examples provided for calculating the area of a window shaded by attached vertical or horizontal projections. For 3:00 PM LST IN July, the solar position calculated in previous examples is

Solar altitude $\beta = 57.2°$

Solar azimuth $\phi = 75.1°$

Surface-solar azimuth $\gamma = 15.1°$

From Chapter 15, Equation (32), profile angle Ω is calculated by

$$\tan\Omega = \tan\beta/\cos\gamma = \tan(57.2)/\cos(15.1) = 1.6087$$

$$\Omega = 58.1°$$

From Chapter 15, Equation (34), shadow height S_H is

$$S_H = P_H \tan\Omega = 3.05(1.6087) = 4.9 \text{ m}$$

Because the window is 1.95 m tall, at 3:00 PM the window is completely shaded by the 3 m deep overhang. Thus, the shaded window heat gain includes only diffuse solar and conduction gains. This is converted to cooling load by separating the radiant portion, applying RTS, and adding the resulting radiant cooling load to the convective portion to determine total cooling load. Those results are in Table 33. The total window cooling load = 322 W.

Part 5. Room cooling load total. Calculate the sensible cooling loads for the previously described office at 3:00 PM in July.

Solution: The steps in the previous example parts are repeated for each of the internal and external loads components, including the southeast-facing window, spandrel and brick walls, the southwest-facing brick wall, the roof, people, and equipment loads. The results are tabulated in Table 34. The total room sensible cooling load for the office is 1077 W at 3:00 PM in July. When this calculation process is repeated for a 24 h design day for each month, it is found that the peak room sensible cooling load actually occurs in July at hour 14 (2:00 PM solar time) at 1077 W as indicated in Table 35.

Although simple in concept, these steps involved in calculating cooling loads are tedious and repetitive, even using the "simplified" RTS method; practically, they should be performed using a computer spreadsheet or other program. The calculations should be repeated for multiple design conditions (i.e., times of day, other months) to determine the maximum cooling load for mechanical equipment sizing. Example spreadsheets for computing each cooling load component using conduction and radiant time series are available from ASHRAE. To illustrate the full building example discussed previously, those individual component spreadsheets have been compiled to allow calculation of cooling and heating loads on a room by room basis as well as for a "block" calculation for analysis of overall areas or buildings where detailed room-by-room data are not available.

9.2 SINGLE-ROOM EXAMPLE PEAK HEATING LOAD

Although the physics of heat transfer that creates a heating load is identical to that for cooling loads, a number of traditionally used simplifying assumptions facilitate a much simpler calculation procedure. As described in the Heating Load Calculations section, design heating load calculations typically assume a single outdoor temperature, with no heat gain from solar or internal sources, under steady-state conditions. Thus, space heating load is determined by computing the heat transfer rate through building envelope elements ($UA\,\Delta T$) plus heat required because of outdoor air infiltration.

Part 6. Room heating load. Calculate the room heating load for the previous described office, including infiltration airflow at one air change per hour.

Solution: Because solar heat gain is not considered in calculating design heating loads, orientation of similar envelope elements may be ignored and total areas of each wall or window type combined. Thus, the total spandrel wall area = 5.57 + 5.57 = 11.14 m^2, total brick wall area = 5.57 + 3.72 = 9.29 m^2, and total window area = 3.72 + 3.72 = 7.44 m^2. For this example, use the U-factors that were used for cooling load conditions. In some climates, higher prevalent winds in winter should be considered in calculating U-factors (see Chapter 25 for information on calculating U-factors and surface heat transfer coefficients appropriate for local wind conditions). The 99.6% heating design dry-bulb temperature for Atlanta is –5.6°C and the indoor design temperature is 22.2°C. The room volume with a 2.74 m ceiling = 2.74 × 12.7 = 33.2 m^3 = 33 200 L. At one air change per hour, the infiltration airflow = 32 200/3600 = 9.2 L/s. Thus, the heating load is

Windows:	3.18 × 7.44 × [22.2 – (–5.6)]	= 658 W
Spandrel wall:	0.44 × 11.14 × [22.2 – (–5.6)]	= 136
Brick wall:	0.45 × 9.29 × [22.2 – (–5.6)]	= 116
Roof:	0.18 × 12.08 × [22.2 – (–5.6)]	= 60
Infiltration:	9.2 × 1.23 × [22.2 – (–5.6)]	= 315
Total room heating load:		1285 W

9.3 WHOLE-BUILDING EXAMPLE

Because a single-room example does not illustrate the full application of load calculations, a multistory, multiple-room example building has been developed to show a more realistic case. A hypothetical project development process is described to illustrate its effect on the application of load calculations.

Table 36 Block Load Example: Envelope Area Summary, m²

	Floor Area	Brick Areas				Spandrel/Soffit Areas				Window Areas

Design Process and Shell Building Definition

A development company has acquired a piece of property in Atlanta, GA, to construct an office building. Although no tenant or end user has yet been identified, the owner/developer has decided to proceed with the project on a speculative basis. They select an architectural design firm, who retains an engineering firm for the mechanical and electrical design.

At the first meeting, the developer indicates the project is to proceed on a fast-track basis to take advantage of market conditions; he is negotiating with several potential tenants who will need to occupy the new building within a year. This requires preparing **shell-and-core** construction documents to obtain a building permit, order equipment, and begin construction to meet the schedule.

The shell-and-core design documents will include finished design of the building exterior (the **shell**), as well as permanent interior elements such as stairs, restrooms, elevator, electrical rooms and mechanical spaces (the **core**). The primary mechanical equipment must be sized and installed as part of the shell-and-core package in order for the project to meet the schedule, even though the building occupant is not yet known.

The architect selects a two-story design with an exterior skin of tinted, double-glazed vision glass; opaque, insulated spandrel glass, and brick pilasters. The roof area extends beyond the building edge to form a substantial overhang, shading the second-floor windows. Architectural drawings for the shell-and-core package (see Figures 17 to 22) include plans, elevations, and skin construction details, and are furnished to the engineer for use in "block" heating and cooling load calculations. Mechanical systems and equipment must be specified and installed based on those calculations. (*Note*: Full-size, scalable electronic versions of the drawings in Figures 17 to 22, as well as detailed lighting plans, are available from ASHRAE at www.ashrae.org and in the ASHRAE Handbook Online version of this chapter, on the Additional Features tab.)

The HVAC design engineer meets with the developer's operations staff to agree on the basic HVAC systems for the project. Based on their experience operating other buildings and the lack of specific information on the tenant(s), the team decides on two variable-volume air-handling units (AHUs), one per floor, to provide operating flexibility if one floor is leased to one tenant and the other floor to someone else. Cooling will be provided by an air-cooled chiller located on grade across the parking lot. Heating will be provided by electric resistance heaters in parallel-type fan-powered variable-air-volume (VAV) terminal units. The AHUs must be sized quickly to confirm the size of the mechanical rooms on the architectural plans. The AHUs and chiller must be ordered by the mechanical subcontractor within 10 days to meet the construction schedule. Likewise, the electric heating loads must be provided to the electrical engineers to size the electrical service and for the utility company to extend services to the site.

The mechanical engineer must determine the (1) peak airflow and cooling coil capacity for each AHU, (2) peak cooling capacity required for the chiller, and (3) total heating capacity for sizing the electrical service.

Solution: First, calculate "block" heating and cooling loads for each floor to size the AHUs, then calculate a block load for the whole building determine chiller and electric heating capacity.

Based on the architectural drawings, the HVAC engineer assembles basic data on the building as follows:

Location: Atlanta, GA. Per Chapter 14, latitude = 33.64, longitude = 84.43, elevation = 313 m above sea level, 99.6% heating design dry-bulb temperature = –5.6°C. For cooling load calculations, use 5% dry-bulb/coincident wet-bulb monthly design day profile from Chapter 14 (on CD-ROM). See Table 27 for temperature profiles used in these examples.

Indoor design conditions: 22.2°C for heating; 23.9°C with 50% rh for cooling.

Building orientation: Plan north is 30° west of true north.

Gross area per floor: 1765 m² first floor and 1459 m² second floor.

Total building gross area: 3224 m².

Windows: Bronze-tinted, double-glazed. Solar heat gain coefficients, U-factors are as in the single-room example.

Walls: Part insulated spandrel glass and part brick-and-block clad columns. The insulation barrier in the soffit at the second floor is similar to that of the spandrel glass and is of lightweight construction; for simplicity, that surface is assumed to have similar thermal heat gain/loss to the spandrel glass. Construction and insulation values are as in single-room example.

Roof: Metal deck, topped with board insulation and membrane roofing. Construction and insulation values are as in the single-room example.

Floor: 127 mm lightweight concrete slab on grade for first floor and 127 mm lightweight concrete on metal deck for second floor

Total areas of building exterior skin, as measured from the architectural plans, are listed in Table 36.

The engineer needs additional data to estimate the building loads. Thus far, no tenant has yet been signed, so no interior layouts for population counts, lighting layouts, or equipment loads are available. To meet the schedule, assumptions must be made on these load components. The owner requires that the system design must be flexible enough to provide for a variety of tenants over the building's life. Based on similar office buildings, the team agrees to base the block load calculations on the following assumptions:

Occupancy: 7.54 people per 100 m² = 13.3 m²/person
Lighting: 11.8 W/m²
Tenant's office equipment: 10.76 W/m²

Normal use schedule is assumed at 100% from 7:00 AM to 7:00 PM and unoccupied/off during other hours.

With interior finishes not finalized, the owner commits to using light-colored interior blinds on all windows. The tenant interior design could include carpeted flooring or acoustical tile ceilings in all areas, but the more conservative assumption, from a peak load standpoint, is chosen: carpeted flooring and no acoustical tile ceilings (no ceiling return plenum).

For block loads, the engineer assumes that the building is maintained under positive pressure during peak cooling conditions and that infiltration during peak heating conditions is equivalent to one air change per hour in a 3.5 m deep perimeter zone around the building.

To maintain indoor air quality, outdoor air must be introduced into the building. Air will be ducted from roof intake hoods to the AHUs where it will be mixed with return air before being cooled and dehumidified by the AHU's cooling coil. ASHRAE *Standard* 62.1 is

the design basis for ventilation rates; however, no interior tenant layout is available for application of *Standard* 62.1 procedures. Based on past experience, the engineer decides to use 9.44 L/s of outdoor air per person for sizing the cooling coils and chiller.

Block load calculations were performed using the RTS method, and results for the first and second floors and the entire building are summarized in Tables 37, 38, and 39. Based on these results, the engineer performs psychrometric coil analysis, checks capacities versus vendor catalog data, and prepares specifications and schedules for the equipment. This information is released to the contractor with the shell-and-core design documents. The air-handling units and chiller are purchased, and construction proceeds.

Tenant Fit Design Process and Definition

About halfway through construction, a tenant agrees to lease the entire building. The tenant will require a combination of open and enclosed office space with a few common areas, such as conference/ training rooms, and a small computer room that will operate on a 24 h basis. Based on the tenant's space program, the architect prepares interior floor plans and furniture layout plans, and the electrical engineer prepares lighting design plans. Those drawings are furnished to the HVAC engineer to prepare detailed design documents. The first step in this process is to prepare room-by-room peak heating and cooling load calculations, which will then be used for design of the air distribution systems from each of the VAV air handlers already installed.

The HVAC engineer must perform a room-by-room "takeoff" of the architect's drawings. For each room, this effort identifies the floor area, room function, exterior envelope elements and areas, number of occupants, and lighting and equipment loads.

The tenant layout calls for a dropped acoustical tile ceiling throughout, which will be used as a return air plenum. Typical 600 by 1200 mm fluorescent, recessed, return-air-type lighting fixtures are selected. Based on this, the engineer assumes that 20% of the heat gain from lighting will be to the return air plenum and not enter rooms directly. Likewise, some portion of the heat gain from the roof will be extracted via the ceiling return air plenum. From experience, the engineer understands that return air plenum paths are not always predictable, and decides to credit only 30% of the roof heat gain to the return air, with the balance included in the room cooling load.

For the open office areas, some areas along the building perimeter will have different load characteristics from purely interior spaces because of heat gains and losses through the building skin.

Although those perimeter areas are not separated from other open office spaces by walls, the engineer knows from experience that they must be served by separate control zones to maintain comfort conditions.

Room-by-Room Cooling and Heating Loads

The room-by-room results of RTS method calculations, including the month and time of day of each room's peak cooling load, as well as peak heating loads for each room and all input data, are available at www.ashrae.org and in the ASHRAE Handbook Online version of this chapter (on the Additional Features tab) in spreadsheet format similar to Table 39. These results are used by the HVAC engineer to select and design room air distribution devices and to schedule airflow rates for each space. That information is incorporated into the tenant fit drawings and specifications issued to the contractor.

Conclusions

The example results illustrate issues that should be understood and accounted for in calculating heating and cooling loads:

- First, peak room cooling loads occur at different months and times, depending on the exterior exposure of the room. Calculation of cooling loads for a single point in time may miss the peak and result in inadequate cooling for that room.
- Often, in real design processes, not all data are known. Reasonable assumptions based on past experience must be made.
- Heating and air-conditioning systems often serve spaces whose use changes over the life of a building. Assumptions used in heating and cooling load calculations should consider reasonable possible uses over the life of the building, not just the first use of the space.
- The relative importance of each cooling and heating load component varies, depending on the portion of the building being considered. Characteristics of a particular window may have little effect on the entire building load, but could have a significant effect on the supply airflow to the room where the window is located and thus on the comfort of the occupants of that space.

10. PREVIOUS COOLING LOAD CALCULATION METHODS

Procedures described in this chapter are the most current and scientifically derived means for estimating cooling load for a defined building space, but methods in earlier editions of the ASHRAE Handbook are valid for many applications. These earlier procedures are simplifications of the heat balance principles, and their use requires experience to deal with atypical or unusual circumstances. In fact, any cooling or heating load estimate is no better than the assumptions used to define conditions and parameters such as physical makeup of the various envelope surfaces, conditions of occupancy and use, and ambient weather conditions. Experience of the practitioner can never be ignored.

The primary difference between the HB and RTS methods and the older methods is the newer methods' direct approach, compared to the simplifications necessitated by the limited computer capability available previously.

The **transfer function method (TFM)**, for example, required many calculation steps. It was originally designed for energy analysis with emphasis on daily, monthly, and annual energy use, and thus was more oriented to average hourly cooling loads than peak design loads.

The **total equivalent temperature differential method with time averaging (TETD/TA)** has been a highly reliable (if subjective) method of load estimating since its initial presentation in the 1967 *Handbook of Fundamentals*. Originally intended as a manual method of calculation, it proved suitable only as a computer application because of the need to calculate an extended profile of hourly heat gain values, from which radiant components had to be averaged over a time representative of the general mass of the building involved. Because perception of thermal storage characteristics of a given building is almost entirely subjective, with little specific information for the user to judge variations, the TETD/TA method's primary usefulness has always been to the experienced engineer.

The **cooling load temperature differential method with solar cooling load factors (CLTD/CLF)** attempted to simplify the two-step TFM and TETD/TA methods into a single-step technique that proceeded directly from raw data to cooling load without intermediate conversion of radiant heat gain to cooling load. A series of factors were taken from cooling load calculation results (produced by more sophisticated methods) as "cooling load temperature differences" and "cooling load factors" for use in traditional conduction ($q = UA\Delta t$) equations. The results are approximate cooling load values rather than simple heat gain values. The simplifications and assumptions used in the original work to derive those factors limit this method's applicability to those building types and conditions for which the CLTD/CLF factors were derived; the method should not be used beyond the range of applicability.

Licensed for single user. © 2021, ASHRAE, Inc.

Although the TFM, TETD/TA, and CLTD/CLF procedures are not republished in this chapter, those methods are not invalidated or discredited. Experienced engineers have successfully used them in millions of buildings around the world. The accuracy of cooling load calculations in practice depends primarily on the availability of accurate information and the design engineer's judgment in the assumptions made in interpreting the available data. Those factors have much greater influence on a project's success than does the choice of a particular cooling load calculation method.

The primary benefit of HB and RTS calculations is their somewhat reduced dependency on purely subjective input (e.g., determining a proper time-averaging period for TETD/TA; ascertaining appropriate safety factors to add to the rounded-off TFM results; determining whether CLTD/CLF factors are applicable to a specific unique application). However, using the most up-to-date techniques in real-world design still requires judgment on the part of the design engineer and care in choosing appropriate assumptions, just as in applying older calculation methods.

CHAPTER 19

ENERGY ESTIMATING AND MODELING METHODS

General Considerations 19.1
Degree-Day and Bin Methods 19.6
Thermal Loads Modeling 19.8
HVAC Component Modeling 19.15
Low-Energy System Modeling 19.24
Data-Driven Modeling 19.27
Model Calibration 19.34
Validation and Testing 19.37

ENERGY requirements of HVAC systems directly affect a building's operating cost and indirectly affect the environment. This chapter discusses methods for estimating energy use for two purposes: modeling for building and HVAC system design and associated design optimization (**forward modeling**), and modeling energy use of existing buildings for establishing baselines, calculating retrofit savings, and implementing model predictive control (**data-driven modeling**) (Armstrong et al. 2006a; Gayeski et al. 2012; Krarti 2010).

1. GENERAL CONSIDERATIONS

1.1 MODELS AND APPROACHES

A mathematical **model** is a description of the behavior of a system. It is made up of three components (Beck and Arnold 1977):

- **Input variables** (statisticians call these *regressor variables*, whereas physicists call them *forcing variables*), which act on the system. There are two types: controllable by the experimenter (e.g., internal gains, thermostat settings), and uncontrollable (e.g., climate).
- **System structure and parameters/properties**, which provide the necessary physical description of the system (e.g., thermal mass or mechanical properties of the elements).
- **Output** (*response*, or *dependent*) variables, which describe the reaction of the system to the input variables. Energy use is often a response variable.

The science of mathematical modeling as applied to physical systems involves determining the third component of a system when the other two components are given or specified. There are two broad but distinct approaches to modeling: forward (classical) and data driven (inverse). The choice of approach is dictated by the objective or purpose of the investigation (Rabl 1988).

Forward (Classical) Approach

The objective is to predict the output variables of a specified model with known structure and known parameters when subject to specified input variables. To ensure accuracy, models have tended to become increasingly detailed. This approach presumes knowledge not only of the various natural phenomena affecting system behavior but also of the magnitude of various interactions (e.g., effective thermal mass, heat and mass transfer coefficients). The main advantage of this approach is that the system need not be physically built to predict its behavior. The forward-modeling approach is ideal in the preliminary design when design details are limited.

Forward modeling of building energy use begins with a physical description of the building system or component of interest. For example, building geometry, geographical location, physical characteristics (e.g., wall material and thickness), type of equipment and operating schedules, type of HVAC system, building operating schedules, plant equipment, etc., are specified. The peak and average energy use of such a building can then be predicted or simulated by the forward-simulation model. The primary benefits of this method are that it is based on sound engineering principles and has gained widespread acceptance by the design and professional community. Major simulation codes, such as DOE-2, EnergyPlus, ESP-r, and TRNSYS are based on forward-simulation models.

Although procedures for estimating energy requirements vary considerably in their degree of complexity, they all have three common elements: calculation of (1) space load, (2) secondary equipment load and energy requirements, and (3) primary equipment energy requirements. Here, *secondary* refers to equipment that distributes the heating, cooling, or ventilating medium to conditioned spaces, whereas *primary* refers to central plant equipment that converts fuel or electric energy to heating or cooling effect.

The space load is the amount of energy that must be added to or extracted from a space to maintain thermal comfort. The simplest procedures assume that the energy required to maintain comfort is only a function of the outdoor dry-bulb temperature. More detailed methods consider humidity, solar effects, internal gains, heat and moisture storage in walls and interiors, and effects of wind on both building envelope heat transfer and infiltration. The section on Thermal Loads Modeling addresses some of these factors. ASHRAE Standard 183 and Chapters 17 and 18 discuss load calculation in detail.

Although energy calculations are similar to the heating and cooling design load calculations used to size equipment, they are not the same. Energy calculations are based on average use and typical weather conditions rather than on maximum use and worst-case weather. Currently, most procedures are based on hourly profiles for climatic conditions and operational characteristics for a number of typical days of the year or on 8760 hours of operation per year.

The space load is converted to a load on the secondary equipment. This can be a simple estimate of duct or piping losses or gains, or a complex hour-by-hour simulation of an air system, such as variable-air-volume with outdoor-air cooling. This step must include calculation of all forms of energy required by the secondary system (e.g., electrical energy to operate fans and/or pumps, energy in heated or chilled water).

The secondary equipment load is converted to the fuel and energy required by the primary equipment and the peak demand on the utility system. It considers equipment efficiencies and part-load characteristics. It is often necessary to keep track of the different forms of energy, such as electrical, natural gas, and/or oil. In some cases, where calculations are required to ensure compliance with codes or standards, these energies must be converted to source energy or resource consumed, as opposed to energy delivered to the building boundary.

Previously, the steps were performed independently: each step was completed for the entire year and hourly results were passed to the next step. Current software usually performs all steps at each time interval, allowing effects such as insufficient plant capacity to be reflected in room conditions.

Often, energy calculations lead to an economic analysis to establish the cost effectiveness of efficiency measures (as in ASHRAE

The preparation of this chapter is assigned to TC 4.7, Energy Calculations.

Licensed for single user. © 2021, ASHRAE, Inc.

Standard 90.1). Thus, thorough energy analysis provides intermediate data, such as time of energy use and maximum demand, so utility charges can be accurately estimated. Although not part of the energy calculations, capital equipment costs should also be estimated to assess the life-cycle costs of alternative efficiency measures.

Data-Driven (Inverse) Approach

In this approach, input and output variables are known and measured, and the objective is to determine a mathematical description of the system and to estimate system parameters. In contrast to the forward approach, the data-driven approach is relevant only when the system has already been built and actual performance data are available for model development, calibration (see the section on Model Calibration), and/or identification. Two types of performance data can be used: nonintrusive and intrusive. **Intrusive data** are gathered under conditions of predetermined or planned experiments on the system to elicit system response under a wider range of system performance than would occur under normal system operation to allow more accurate model identification. When constraints on system operation do not allow such tests to be performed, the model must be identified from **nonintrusive data** obtained under normal operation.

The data-driven model has to meet requirements very different from the forward model. The data-driven model can only contain a relatively small number of parameters because of the limited and often repetitive information contained in the performance data. (For example, building operation from one day to the next is fairly repetitive.) It is thus a much simpler model that contains fewer terms representative of aggregated or macroscopic parameters (e.g., overall building heat loss coefficient and time constants). Because model parameters are deduced from actual building performance, it is much more likely to accurately capture as-built system performance, thus allowing more accurate prediction of future system behavior under certain specific circumstances. Performance data collection and model formulation need to be appropriately tailored for the specific circumstance, which often requires a higher level of user skill and expertise. In general, data-driven models are less flexible than forward models in evaluating energy implications of different design and operational alternatives, and so are not substitutes in this regard.

To better understand the uses of data-driven models, consider some of the questions that a building professional may ask about an existing building with known energy consumption (Rabl 1988):

- How does energy consumption compare with design predictions (and are any discrepancies caused by anomalous weather, unintended building operation, improper operation, as-built deficiency, etc.)?
- How would consumption change if thermostat settings, ventilation rates, or indoor lighting levels were changed?
- How much energy could be saved by retrofits to the building shell, changes to air handler operation from constant volume (CV) to variable air volume (VAV), or changes in the various control settings?
- If retrofits are implemented, can one verify that the savings are due to the retrofit and not to other causes (e.g., weather)?
- How can one detect faults in HVAC equipment and optimize control and operation?

All these questions are better addressed by the data-driven approach. The forward approach could also be used, for example, by going back to the blueprints of the building and of the HVAC system, and repeating the analysis performed at the design stage using actual building schedules and operating modes, but this is tedious and labor intensive, and materials and equipment often perform differently in reality than as specified. Tuning the forward-simulation model is often problematic, although it is an option (see the section on Model Calibration).

1.2 OVERALL MODELING STRATEGIES

In developing a simulation model for building energy prediction, two basic issues must be considered: (1) modeling components or subsystems and (2) overall modeling strategy. Modeling components, discussed in the sections on Thermal Loads Modeling and HVAC Component Modeling, results in sets of equations describing the individual components. The overall modeling strategy refers to the **sequence** and **procedures** used to solve these equations. The accuracy of results and the computer resources required to achieve these results depend on the modeling strategy.

Early building energy programs, including some still in common use, execute load models for every space for every hour of the simulation period. (Most models of this type use 1 h as the time step, which excludes any information on phenomena occurring in a shorter time span.) Next, the program runs models for every secondary system, one at a time, for every hour of the simulation. Finally, the plant simulation model is executed again for the entire period.

This procedure is shown in Figure 1. Solid lines represent data passed from one model to the next; dashed lines represent information, usually provided by the user, about one model passed to the preceding model. For example, the system information may consist of a piecewise-linear function of zone temperature that gives system capacity.

Because of this loads-systems-plants sequence, certain phenomena cannot be modeled precisely. For example, if the heat balance method for computing loads is used, and some component in the system simulation model cannot meet the load, the program can only report the current load. In actuality, the space temperature should readjust until the load matches equipment capacity, but this cannot be modeled, because loads have been precalculated and fixed. If the weighting-factor method is used for loads, this problem is partially overcome, because loads are continually readjusted during the system simulation. However, the weighting-factor technique is based on linear mathematics, and wide departures of room temperatures from those used during execution of the load program can introduce errors.

A similar problem arises in plant simulation. For example, in an actual building, as load on the central plant varies, the supply chilled-water temperature also varies. This variation in turn affects the capacity of secondary system equipment. In an actual building, when the central plant becomes overloaded, space temperatures should rise to reduce load. However, with this separate load-system-plant approach, this condition cannot occur; thus, only the overload condition can be reported. These are some of the penalties associated with decoupling the load, system, and plant models.

More recent building energy programs use an alternative strategy, in which all calculations are performed at each time step. Here, the load, system, and plant equations are solved simultaneously at each time interval. With this strategy, unmet loads and imbalances cannot occur; conditions at the plant are immediately reflected to the secondary system and then to the load model, forcing them to readjust to the instantaneous conditions throughout the building. The results of this modeling strategy are superior, although the magnitude and importance of the improvement are case specific.

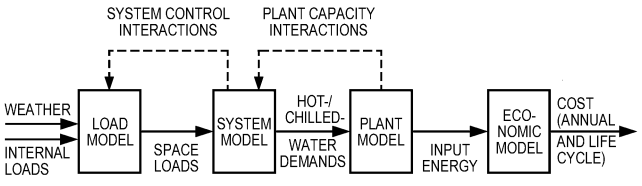

Fig. 1 Overall Modeling Strategy

Licensed for single user. © 2021, ASHRAE, Inc.

The principal disadvantage of this approach, and the reason that it was not widely used in the past, is that it demands more computing resources. However, most current desktop computers can now run programs using the alternative approach in a reasonable amount of time. Programs that, to one degree or another, implement simultaneous solution of the loads, system, and plant models have been developed by ESRU (2016), Klein et al. (1994), Park et al. (1985), Taylor et al. (1990, 1991), and U.S. Department of Energy (1996-2016). Some of these programs can simulate the loads, systems, and plants using subhourly time steps.

An economic model, as shown in Figure 1, calculates energy costs (and sometimes capital costs) based on the estimated required input energy. Thus, the simulation model calculates energy use and cost for any given input weather and internal loads. By applying this model (i.e., determining output for given inputs) at each hour (or other suitable interval), the hour-by-hour energy consumption and cost can be determined. Maintaining running sums of these quantities yields monthly or annual energy usage and costs.

Because detailed models are computationally intensive, several simplified methods have been developed, including the degree-day, bin, and correlation methods. See the section on Degree-Day and Bin Methods for more information.

1.3 SIMULATING SECONDARY AND PRIMARY SYSTEMS

Traditionally, most energy analysis programs include a set of preprogrammed models that represent various systems (e.g., variable air volume, terminal reheat, multizone, variable refrigerant flow). In this scheme, the equations for each system are arranged so they can be solved sequentially. If this is not possible, the smallest number of equations that must be solved simultaneously is solved using an appropriate technique. Furthermore, individual equations may vary hourly in the simulation, depending on controls and operating conditions. For example, a dry coil uses different equations than a wet coil. The primary disadvantage of this scheme is that it is relatively inflexible: to modify a system, the program source code may have to be modified and recompiled.

An alternative strategy views the system as a series of components (e.g., fan, coil, pump, duct, pipe, damper, thermostat) that may be organized in a component library (Park et al. 1985; TRNSYS 2012). Users specify connections between the components, and the program then resolves the specification of components and connections into a set of simultaneous equations.

A refinement of component-based modeling is known as **equation-based modeling** (Buhl et al. 1993; Sowell and Moshier 1995). These models do not follow predetermined rules for a solution, and the user can specify which variables are inputs and which are outputs. Current research in this area centers on use of the Modelica object-oriented modeling language (Wetter et al. 2011).

1.4 HISTORY OF SIMULATION METHOD DEVELOPMENT

Significant historical events, such as World Wars I and II, the development of analog and digital computers and programming languages (1950s), and repeated oil crises (1967, 1973, and 1979) spurred the development of analysis methods and computer simulation programs now used to simulate building energy use. Before the 1950s, most of the fundamentals (i.e., gas laws, heat transfer properties, and thermodynamics) of today's HVAC systems had been studied and published, which contributed significantly to the rapid development of today's building energy simulation technology. Also, during this same period, researchers and engineers developed the essential methods for calculating and analyzing the dynamic heat gain through multilayer walls, overall dynamic building cooling and heating loads, solar heating performance, and internal reflected illuminance (Oh 2013; Oh and Haberl 2016a, 2016b, 2016c).

In the 1920s, one of the most important methods for calculating the dynamic heat gain through walls and roofs for whole-building energy simulation [i.e., the response factor method (RFM)] was developed and published by André Nessi and Léon Nisolle at École Centrale Paris (French University) in France (Nessi and Nisolle 1925). The RFM concept is widely used in most of today's cooling and heating loads calculations, such as with the weighting factor method or the transfer function method (Mitalas and Stephenson 1967; Stephenson and Mitalas 1967, 1971) used in DOE-2.1E (Winkelmann et al. 1993), DOE-2.2/eQUEST (LBNL 1998), TRACE (Trane 2013), and HAP (Carrier 2013); the CLTD/CLF method used in TRACE; the heat balance method (Pedersen et al. 1997) used in BLAST (Hittle 1977) and EnergyPlus (Crawley et al. 2001); and the radiant time series method (Spitler et al. 1997) used in TRACE. In the 1940s, the concept of the resistance-capacitance (RC) network analysis method (i.e., the thermal network method) used in simulation programs for buildings was first introduced by Victor Paschkis, a research engineer at Columbia University (Paschkis 1942; Paschkis and Baker 1942). The thermal network concept is widely used today in whole-building simulation programs such as DOE-2.1E, DOE-2.2/eQUEST, and EnergyPlus and in detailed solar simulation programs such as TRNSYS and SUNREL (Deru et al. 2002).

In the 1950s, the most important method (i.e., the utilizability method) for calculating the performance of solar heating systems for design programs was developed (Whillier 1953). The utilizability method is used today in simplified solar design programs such as RETScreen (NRC 2004), F-Chart (Klein and Beckman 2001a), and PV F-Chart (Klein and Beckman 2001b).

Also during the 1950s, analog computers were first used to study the behavior of dynamic heat gain/loss and the impact of dynamic heat gain/loss on HVAC systems (Buchberg 1955, 1958; Nottage and Parmelee 1954; Willcox et al. 1954). During the 1960s, digital computers and the analysis methods suitable for the digital computers were developed and became widely used. Digital computers were quickly substituted for analog computers during this period because the digital computer was more convenient to program, more flexible, and more agile at describing the governing equations and driving functions than the methods used in analog computers. Finally, the scientific applications of the digital computer were considerably improved by the FORTRAN programming language, a high-level, scientific programming language that was first commercially released in 1957 by IBM. In the 1960s, FORTRAN allowed computer codes written on one computer to be run on another computer by a different analyst, which accelerated the wide-spread availability of building energy simulation programs. The combination of computer advances with the analysis methods developed by numerous researchers facilitated the development of today's whole-building energy, solar energy, and daylighting simulation programs.

1.5 USING ENERGY MODELS

Typical Applications

Energy models are useful for a range of applications, and the typical application of forward-modeling tools falls into three categories:

- **Comparison.** A common application is to use energy models to compare the estimated performance of design alternatives for new buildings or to compare retrofit alternatives for existing buildings. In such design studies, the goal is to estimate the relative performance of two or more options. Examples include comparing alternatives for building form and orientation, comparing different glazing selections, or comparing chiller alternatives. Energy models are especially well suited to such comparison studies,

Licensed for single user. © 2021, ASHRAE, Inc.

because the relative performance is likely to be estimated with reasonable accuracy even if some inputs, such as actual operating hours or plug loads, are not accurately known at the time of the study.

- **Compliance.** Using models for energy code compliance (e.g., ASHRAE *Standard* 90.1) and for building rating system credit (e.g., U.S. Green Building Council's LEED® rating system) are very common applications. In most cases, these studies involve comparing two energy models: one representing a baseline building that meets the minimum code requirements, and the other representing the proposed building design, with the result an estimate of relative performance. Some utility and other incentive programs also use the same method for estimating energy savings for new and retrofit construction projects. Note that the models will not necessarily be good predictors of actual energy use unless the inputs have been carefully specified to represent the expected operation of the actual building.
- **Prediction.** An application of growing importance is using energy models to predict energy consumption. Some industry efforts, such as Architecture 2030 (AIA 2014), encourage building designers to set targets for energy consumption. In those cases, the goal is to design a building that meets an absolute energy target, often specified in terms of $kWh/m^2 \cdot yr$. In addition, some owners seek zero-energy buildings that offset consumption with renewable energy. During the design of zero-energy buildings, accurate prediction of energy consumption is important for proper sizing of renewable energy systems. Energy models used for prediction require very careful attention to providing realistic inputs to represent the expected building operation.

Choosing Measures for Evaluation

Forward-modeling programs are useful for evaluating many types of design elements, whereas they may be unnecessary or inappropriate for evaluating other elements. They are most useful for evaluating elements that affect heating and cooling loads. Many programs also provide the ability to compare the energy performance of different HVAC designs. The following are examples of design elements that are typically good candidates for evaluation with forward-modeling programs:

- **Building form and orientation.** Varying building dimensions.
- **Opaque envelope.** Varying levels of insulation and thermal mass.
- **Fenestration.** Alternative glazing and framing types, and both fixed and operable shading devices.
- **Daylighting controls.** Requires a program with an adequately accurate daylight illuminance calculation.
- **Cooling equipment efficiency**. Full- and partial-load performance.
- **Heating equipment efficiency**. Full- and partial-load performance, condensing versus noncondensing equipment.
- **Economizer cooling**. Air- and water-side economizers.
- **Variable-flow controls**. Air and hydronic distribution system control.
- **Basic HVAC controls.** Space temperature set points, HVAC supply temperature reset controls, start/stop scheduling, load management scheduling.
- **Combined heat and power systems.** Some programs can apply waste heat from cogeneration systems to building thermal demands.

Some design elements do not necessarily require an energy model for evaluation, and a reasonably accurate savings estimate may be possible using other methods. Although it may still be useful to represent them in an energy model along with other measures, it may not be worth the effort for an analysis looking exclusively at these measures:

- **Plug loads.** The majority of the impact is from direct savings that may be calculated simply with an estimate of connected power and operating hours. An energy model may be appropriate if the effect on heating and cooling loads is expected to be significant.
- **Interior lighting power.** Similar issues to plug loads.
- **Exterior lighting power and control.** Has no effect on heating and cooling loads.
- **Control of constant-speed/constant-volume equipment.** The savings from an adjustment in flow may be simple to calculate without using an energy model.
- **Photovoltaic and other on-site generation systems.** Although some programs offer the capability to model photovoltaic systems or other on-site electricity production, separate calculations may be equally accurate and require less effort.

Limitations to the capabilities of most forward-modeling programs are important to understand. Some programs may not be appropriate candidates for performing an evaluation, depending on the feature to be analyzed:

- **Daylight-redirecting devices**. Design elements such as light shelves or light-redirecting glazing are sometimes used to increase the daylighted area. It is important to understand the capabilities of the tool used for analysis.
- **Dynamic glazing**. Dynamic glazing may be used to control glare and solar heat gain. It is important to understand the capabilities of the modeling tool for this design element.
- **Natural ventilation**. Not all programs can model natural ventilation or the integration of mechanical and natural ventilation. See the section on Natural Ventilation for more information.
- **Specific HVAC system types**. The selected program might not have the ability to explicitly model a desired HVAC system configuration.
- **Specific HVAC system control strategies**. Programs vary in capability to represent varying control strategies.

When to Use Energy Models

Energy modeling has appropriate applications throughout the stages of design, construction, and operation of a building. At the earliest conceptual design phase, comparative studies help designers compare options for building form, system types, and other decisions that will be hard to change at later stages. During subsequent phases, energy modeling studies can be used to refine design decisions such as component specifications. At the conclusion of design, the models can be used to document energy code or rating-system compliance. Although use of energy models during construction is less common, their use during commissioning to compare expected performance to observed performance is growing. Similarly, building performance can be verified by comparing actual energy consumption to modeled performance, and any observed differences can help the building operator identify potential areas for improvement. The American Institute of Architects has published a guide to integrating energy modeling in the design process (AIA 2012). Proposed ASHRAE *Standard* 209P specifies mandatory and optional modeling tasks for new construction projects.

Energy Modelers

Creation of energy models has typically been done by specialists, and specialists continue today to perform a significant amount of energy modeling work. However, increasing user-friendliness of modeling software and the integration of building information models and energy modeling tools have made energy modeling more accessible to nonspecialists.

Anyone performing energy modeling should understand the way their program of choice works, understand assumptions being used by the program, and know how to interpret the results obtained from the program.

Licensed for single user. © 2021, ASHRAE, Inc.

ASHRAE offers a Building Energy Modeling Professional (BEMP) qualification exam for modeler certification (www.ashrae.org/education--certification/certification/bemp-building-energy-modeling-professional-certification).

1.6 UNCERTAINTY IN MODELING

Uncertainty is inherent in modeling. When modeling a complex system, there are often uncertainties in identifying system inputs. In addition, there are uncertainties and variability in known model input parameters, and uncertainties in the model itself. It is important for modelers to characterize the uncertainties to understand how to interpret the uncertainty in the model prediction (Macdonald and Strachan 2001; de Wit and Augenbroe 2002). In reporting a model prediction, providing a value without providing its confidence interval implies 0% uncertainty, which is not possible because of many inherent uncertainties in the modeling process. Therefore, it is advisable to provide the predicted value as an interval rather than a precise value.

Uncertainties can be broken into two broad categories: aleatoric and epistemic (Kiureghaian and Ditlevsen 2009). **Aleatoric** uncertainties are those related to inherent randomness and variability of the system and the inputs to the system that cannot be reduced by better knowledge or system observation. They are typically characterized by probabilities. In other words, aleatoric uncertainties are "unknown unknowns." Examples of these in energy modeling are weather-related model inputs or occupant-related loads. **Epistemic** uncertainties are those related to uncertainty of the system model itself or parameters to the model that are fixed/static but not known precisely and that could be reduced with better knowledge of the system or the inputs. Epistemic uncertainty is also referred to as **state-of-knowledge** uncertainty, **subjective** uncertainty, or **reducible** uncertainty. In other words, epistemic uncertainties are "known unknowns." Examples include building geometry, thermal properties of enclosure materials, or efficiencies of equipment (Hopfe and Hensen 2011; Sun et al. 2014). Knowing the type of uncertainty associated with a parameter is important in understanding how to propagate that uncertainty through the model. Uncertainties can be propagated through a model using a variety of methods, including Monte Carlo, importance sampling, local expansion, most-probable-point methods, and numeric integration (Lee and Chen 2008). When using "black box" simulation engines, Monte Carlo methods and importance sampling are the most applicable.

Once the prediction uncertainty is quantified, there are various uses for the information. The output can be analyzed to obtain most probable values and/or variances. Output probability distributions can be analyzed for understanding the risk of underperformance. Uncertainty statistics can also be used for verifying that a model meets standards or guidelines for baseline predictions in measurement and verification, along with determining the uncertainty in cost savings calculations. ASHRAE *Guideline* 14 provides instruction on maximum levels of uncertainty in baseline models, along with simplified methods for assessing the quantifiable uncertainty in savings computations.

1.7 CHOOSING AN ANALYSIS METHOD

The most important step in selecting an energy analysis method is matching method capabilities with project requirements. The method must be capable of evaluating all design options with sufficient accuracy to make correct choices. The following factors apply generally (Sonderegger 1985):

- **Accuracy.** The method should be sufficiently accurate to allow correct choices. Because of the many parameters involved in energy estimation, absolutely accurate energy prediction is not possible (Waltz 1992). ANSI/ASHRAE *Standard* 140 was developed to identify and diagnose differences in predictions that may be caused by algorithmic differences, modeling limitations, coding errors, or input errors. More information on model validation and testing can be found in the Validation and Testing section of this chapter and in ANSI/ASHRAE *Standard* 140.
- **Sensitivity.** The method should be sensitive to the design options being considered. The difference in energy use between two choices should be adequately reflected.
- **Versatility.** The method should allow analysis of all options under consideration. When different methods must be used to consider different options, an accurate estimate of the differential energy use cannot be made.
- **Speed and cost.** The total time (gathering data, preparing input, calculations, and analysis of output) to make an analysis should be appropriate to the potential benefits gained. With greater speed, more options can be considered in a given time. The cost of analysis is largely determined by the total time of analysis.
- **Reproducibility.** The method should not allow so many vaguely defined choices that different analysts would get completely different results (Corson 1992).
- **Ease of use.** This affects both the economics of analysis (speed) and the reproducibility of results.

Selecting Energy Analysis Computer Programs

Selecting a building energy analysis program depends on its application, number of times it will be used, experience of the user, and hardware available to run it. The first criterion is the ability of the program to deal with the application. For example, if the effect of a shading device is to be analyzed on a building that is also shaded by other buildings part of the time, the ability to analyze detached shading is an absolute requirement, regardless of any other factors.

The cost of the computer facilities and the software itself are typically a small part of running a building energy analysis; the major costs are of learning to use the program and of using it. Major issues that influence the cost of learning a program include (1) complexity of input procedures, (2) quality of the user's manual, and (3) of a good support system to answer questions. As the user becomes more experienced, the cost of learning becomes less important, but the need to obtain and enter a complex set of input data continues to consume the time of even an experienced user until data are readily available in electronic form compatible with simulation programs.

Complexity of input is largely influenced by the availability of default values for the input variables. Default values can be used as a simple set of input data when detail is not needed or when building design is very conventional, but additional detail can be supplied when needed. Secondary defaults, which can be supplied by the user, are also useful in the same way. Some programs allow the user to specify a level of detail. Then the program requests only the information appropriate to that level of detail, using default values for all others. However, whenever default values are used, even internally in the software, the user should take care to understand the default values and whether they apply to the situation being analyzed.

Quality of output is another factor to consider. Reports should be easy to read and uncluttered. Titles and headings should be unambiguous. Units should be stated explicitly. The user's manual should explain the meanings of data presented. Graphic output can be very helpful. In most cases, simple summaries of overall results are the most useful, but very detailed output is needed for certain studies and also for debugging program input during the early stages of analysis.

Before a final decision is made, manuals for the most suitable programs should be obtained and reviewed, and, if possible, demonstration versions of the programs should be obtained and run, and

Licensed for single user. © 2021, ASHRAE, Inc.

support from the software supplier should be tested. The availability of training should be considered when choosing a more complex program.

Availability of weather data and a weather data processing subroutine or program are major features of a program. Some programs include subroutine or supplementary programs that allow the user to create a weather file for any site for which weather data are available. Programs that do not have this capability must have weather files for various sites created by the program supplier. In that case, the available weather data and the terms on which the supplier will create new weather data files must be checked. More information on weather data can be found in Chapter 14.

Auxiliary capabilities, such as economic analysis and design calculations, are a final concern in selecting a program. An economic analysis may include only the ability to calculate annual energy bills from utility rates, or it might extend to calculations or even to life-cycle cost optimization. An integrated program may save time because some input data have been entered already for other purposes.

Results of computer calculations should be accepted with caution, because software vendors do not accept responsibility for the correctness of calculation methods and have no control over program use. Manual calculation should be done to develop a good understanding of underlying physical processes and building behavior. In addition, the user should (1) review the computer program documentation to determine what calculation procedures are used, (2) compare results with manual calculations and measured data, and (3) conduct sample tests to confirm that the program delivers acceptable results.

The most accurate methods for calculating building energy consumption are the costliest because of their intense computational requirements and the expertise needed by the designer or analyst. Simulation programs that assemble component models into system models and then exercise those models with weather and occupancy data are preferred by experts for determining energy use in buildings.

Often, energy consumption at a system or whole-building level must be estimated quickly to study trends, compare systems, or study building effects such as envelope characteristics. For these purposes, simpler methods, such as degree-day and bin, may be used.

The International Building Performance Simulation Association (IBPSA-USA) maintains a website (www.buildingenergysoftwaretools.com) (IBPSA 2015) with information about hundreds of available software tools. Crawley et al. (2005) compare the capabilities of many building simulation tools.

2. DEGREE-DAY AND BIN METHODS

2.1 DEGREE-DAY METHOD

As described in Huang et al. (2001), the degree-day method was developed in the 1930s to estimate the heating energy consumption of a building. A degree-day is a measure of how often and by how many degrees the average daily temperature (the average of the daily maximum and minimum) for a location is above (for cooling) or below (for heating) a base temperature. For example, a day where the average daily temperature is 12 degrees lower than the base temperature would represent 12 degree-days; an equivalent would be 2 days, each of which was 6 degrees below the base temperature. A year's summation of the number of heating or cooling degree-days for a location is a convenient single number indicating that location's climate severity. The base temperature is that at which the building's internal heat gains counterbalance the heat losses to the outdoors, so that the building requires neither heating nor cooling. Below that "balance point" temperature, the building requires heating, whereas above that temperature the building requires cooling, in proportion to the difference from the base temperature.

Base 18°C heating degree-days and, to a lesser extent, base 18°C cooling degree-days have become widely accepted as the most convenient, simple indicators of climate severity. In the United States, heating degree-days vary from fewer than 500 in Miami, FL, 1000 to 3000 in the south, and 3000 to 7000 in the north, to extremes of more than 8000 in Bismarck, ND and 10 000 in Anchorage, AK. Correspondingly, cooling degree-days vary from 0 in Anchorage, AK, to fewer than 100 in Seattle, WA, 500 to 1200 in the north, 1200 to 3000 in the south, and more than 3000 in Phoenix, AZ and Miami, FL.

In the degree-day method, the building heat load (i.e., the amount of heating energy input or cooling energy extraction) is estimated as the number of degree-days times 24 (to convert to degree-hours), times the overall building heat loss coefficient W/K. The overall heat loss coefficient is the sum of the U-factor × area for all external surfaces, such as walls, windows, doors, roof, and losses or gains from infiltration. The cooling load equation is similar but uses cooling degree-days instead of heating degree-days.

Example 1. Estimate the heating energy requirements for an 170 m^2 residence in Denver (3300 K-days) using the degree-day method. The volume of the residence is 400 m^3, the overall heat loss coefficient is 200 W/K, 0.7 air changes per hour (ach). The residence is heated by a furnace with an AFUE of 0.78, with an average duct loss factor of 0.10.

Solution:

The heating load equation is

$$Q_h = \mathrm{HDD}_{65}\left(24\frac{\mathrm{h}}{\mathrm{day}}\right) \times \left(\sum_i U_i A_i + \text{Infiltration air changes/h} \times \text{Volume} \times \text{Volumetric heat capacity for air}\right)$$

To derive the heating or cooling energy consumption, the heating or cooling loads must be divided by the efficiencies of the HVAC system.

$$Q_h = \frac{3300(24)[200 + 0.7(400)(1/3600)(1210)]}{0.78 \times 0.9} = 33\ 200\ \mathrm{kWh}$$

The degree-day method, as demonstrated in Example 1, is limited in that it does not consider the effects of solar heat gain or building thermal mass, nor can it account for variations in infiltration rates, thermostat settings (such as night setback), or occupant actions such as window venting on cool summer nights or during the spring and fall seasons.

Efforts to improve the degree-day method, such as by using variable base temperatures, calculating degree-hours instead of days, etc., are described in the following section. The gains in accuracy from these modifications have been offset by increased difficulty in computation, nearly always requiring a computer program. Because the capability of personal computers has grown to handle programs using methods that capture the transient heat flows that dominate building thermal processes, degree-day methods have fallen increasingly out of favor, because they remain fundamentally steady-state calculations.

Even with these limitations, the degree-day method can still be of use in providing a quick answer that can be used as a starting point or check for more detailed calculations. The degree-day method may be adequate for cases in which gathering the additional data on climate and building conditions may be unwarranted or impractical, such as for estimating heating energy use in light-construction residential buildings with low solar gain in cold

climates. The degree-day method can also be useful in analyzing results from more detailed, often hard-to-interpret calculations.

Variable-Base Degree-Day Method

Further described in Huang et al. (2001), the variable-base degree-day (VBDD) method accounts for balance point temperatures varying between buildings and even within a building, depending on the time of day. The 18°C base temperature is based on the assumption that heat gains from the sun and internal processes contribute on average 3 K of "free heat," allowing a set point of 21°C with heating required only when the outdoor temperature drops below 18°C. Better-insulated, more airtight buildings can have lower balance point temperatures.The average balance point temperature for modern residential buildings is now 13 to 14°C. Commercial buildings' low surface-to-volume ratios, high window-to-wall ratios, and high internal gains allow balance point temperatures of 10°C or lower.

Balance point temperatures differ markedly between daytime and nighttime hours. Figure 2 shows the variation of the balance point temperature for a typical house (Nisson and Dutt 1985). In daytime, the house receives heat gain from the sun and from occupant activity (e.g., equipment, lights). The balance point temperature may be around 8 K below the indoor temperature set point. However, at night, with no solar heat gain and reduced human activity, it may be only 2 K lower than set point. The variation can be even greater for commercial buildings because of higher internal heat gains during the day and very low heat gains at night.

The VBDD method accounts for these different building conditions by calculating (1) the balance point temperature of a building and (2) the heating and cooling degree-hours at that temperature. To divide the daytime and nighttime, degree-hours must be used instead of degree-days. Instead of using the average between the daily maximum and minimum temperatures as for degree-days, degree-hours are calculated from the temperature for each hour. The number of degree-hours divided by 24 can be slightly to significantly larger than the number of degree-days at the same base temperature. An example of why this can occur is a spring day where the average daily temperature may be below the base temperature, but several afternoon hours are above it. Such a day would have no cooling degree-days but a number of cooling degree-hours; these differences can be particularly significant for cooling. The calculations are repeated for daytime and nighttime conditions for each month of the year using degree-hour totals for each period with different base temperatures.

For cooling, the VBDD method can be adjusted to identify the number of cooling degree hours that are actually met by the HVAC system. The cooling balance point changes dramatically depending on whether the building is being vented. If the windows are open, heat gains are flushed from the building and do not affect its cooling load. However, if the windows are closed, solar and internal gains make the balance temperature significantly lower than the thermostat set point for cooling. The VBDD method accounts for these different conditions by calculating the cooling degree-hours using the balance temperature with the windows closed, but not counting degree-hours when the temperatures are below the thermostat set point, when the windows are assumed to be open. Figure 3 shows the one-to-one relationship between cooling degree-hours and the temperature difference between the balance point and outdoor air temperature. Those degree-hours occurring in the ventilation section when the outdoor temperatures are below the thermostat set point are not added to the running total of cooling degree-hours.

VBDD method calculations are, in most cases, too tedious for either hand calculations or implementation in a spreadsheet. In the early 1980s, several PC programs were written using the VBDD method, such as CIRA (Computerized Instrumented Residential Audit) (Sonderegger et al. 1982). Variable-base degree-day programs such as CIRA represent the apex of the VBDD method's application; however, it remains a steady-state method that does not recognize a building's thermal history.

Sources of Degree-Day Data

The most general and directly usable source for degree-day data is the ASHRAE Weather Data Viewer DVD (ASHRAE 2013). This application performs useful aggregations for more than 6000 locations. In addition to design conditions, the Weather DataViewer derives annual and monthly degree-days relative to any base temperature, and also provides bin data. Results are in spreadsheet form. Precalculated annual and monthly degree-days for several common bases are included in the climatic data that accompany Chapter 14, and additional online and printed collections of climatic data are listed in the section on Other Sources of Climatic Information in that chapter.

Annual and monthly degree-days relative to an arbitrary base can be estimated using the Weather Data Viewer or the procedures documented in the section on Estimation of Degree-Days in Chapter 14. Other degree-day estimation methods include the Erbs et al. (1983) model, which needs as input only the average $\bar{t}_o$ for each month of the year.

2.2 BIN AND MODIFIED BIN METHODS

For many applications, the degree-day or variable-base degree-day methods should not be used, because the overall building heat loss coefficient K_{tot}, the efficiency η_h of the HVAC system, or the balance point temperature t_{bal} may not be sufficiently constant. Heat pump efficiency, for example, varies strongly with outdoor temperature; efficiency of HVAC equipment may be affected indirectly by the outdoor temperature t_o when efficiency varies with load (common for boilers and chillers). Furthermore, in most commercial buildings, occupancy has a pronounced pattern that affects heat gain, indoor temperature, and ventilation rate.

In such cases, steady-state calculation can yield good results for annual energy consumption if different temperature intervals and time periods are evaluated separately. This approach is known as the **bin method**, because consumption is calculated for several values of t_o and multiplied by the number of hours N_{bin} in the temperature interval (bin) centered on that temperature:

$$Q_{bin} = N_{bin} \frac{K_{tot}}{\eta_h} [t_{bal} - t_o]^+ \quad (1)$$

The superscript plus sign indicates that only positive values are counted; no heating is needed when t_o is above t_{bal}. Equation (1) is evaluated for each bin, and the total consumption is the sum of the Q_{bin} over all bins. The underlying assumption of the bin method is that, for a given temperature at the same general time of day (morning, afternoon, evening, etc.), the heating and cooling loads of a building should be roughly the same. Therefore, one can derive a building's annual heating and cooling loads by calculating its loads for a set of "snapshots" defined by temperature "bins," multiplying the calculated loads by the number of hours represented by each bin, and then totaling the sums to derive the building's annual heating and cooling loads. Table 1 provides sample annual bin data for several U.S. sites.

In the original formulation of the bin method, there was no accounting for effects such as occupancy, solar gain, or wind on the calculated loads. The **modified bin method** (Knebel 1983) extended the basic bin method to account for weekday/weekend and partial-day occupancy effects, to calculate net building loads (conduction, infiltration, internal loads, and solar loads) at four temperatures, rather than interpolate from design values, and to better describe secondary and primary equipment performance. Other versions of the bin method accounted for solar and wind effects by using more detailed binned data that gave the average wind speeds and solar gains by month, and the number of hours within bins disaggregated by month as well as time of day. Vadon et. al (1991) also presented an improvement for correlating the solar gains to the temperature bins.

Example 2. Estimate the energy requirements for a residence with a design heat loss Q_{des} of 11 700 W at 30°C design temperature difference. The indoor design temperature is 21°C. Average internal heat gains are estimated to be 1250 W. Assume a 10.5 kW heat pump with the char-acteristics given in Columns E and H of Table 2 and in Figure 4.

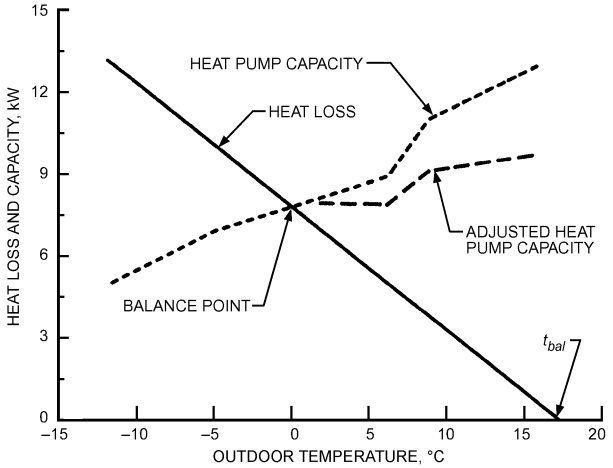

Fig. 4 Heat Pump Capacity and Building Load

Solution: The design heat loss is based on no internal heat generation. The heat pump system energy input is the net heat requirement of the space (i.e., envelope loss minus internal heat generation). The net heat loss per degree and the heating/cooling balance temperature may be computed:

$$K_{tot} = Q_{des}/\Delta t = 11\ 700/30 = 390\ \text{W/K}$$

The balance temperature t_{bal} is defined as the temperature at which the external heat loss equals the internal heat gain Q_{int}, and therefore

$$Q_{int} = K_{tot}(t_o - t_{bal})$$

and

$$t_{bal} = t_o - (Q_{int}/K_{tot})$$

thus

$$t_{bal} = 21 - (1250/390) = 17.8°\text{C}$$

Table 2 is then computed, resulting in 7618 kWh.

3. THERMAL LOADS MODELING

3.1 SPACE SENSIBLE LOAD CALCULATION METHODS

Calculating instantaneous space sensible load is a key step in any building energy simulation. The **heat balance, comprehensive room transfer function (CRTF)**, and **weighting-factor methods** are used for these calculations. A fourth method, the **thermal-network method**, is similar in rigor to the heat balance and CRTF methods but not as widely used.

[h]Column N = Column K + Column M

The **instantaneous space sensible load** is the rate of heat flow into the space air mass. This quantity, sometimes called the *cooling load*, differs from heat gain, which usually contains a radiative component that passes through the air and is absorbed by other bounding surfaces. Instantaneous space sensible load is entirely convective; even loads from internal equipment, lights, and occupants enter the air by convection from the surface of such objects or by convection from room surfaces that have absorbed the radiant component of energy emitted from these sources. However, some adjustment must be made when radiant cooling and heating systems are evaluated because some of the space load is offset directly by radiant transfer without convective transfer to the air mass.

For equilibrium, the instantaneous space sensible load must match the heat removal rate of the conditioning equipment. Any imbalance in these rates changes the energy stored in the air mass. Customarily, however, the thermal mass (heat capacity) of the air itself is ignored in analysis, so the air is always assumed to be in thermal equilibrium. Under these assumptions, the instantaneous space sensible load and rate of heat removal are equal in magnitude and opposite in sign.

The weighting-factor, CRTF, and heat balance methods use conduction transfer functions (or their equivalents) to calculate transmission heat gain or loss. The main difference is in the methods used to calculate the subsequent internal heat transfers to the room. Experience has shown that all the methods produce similar results, provided model coefficients are determined for the specific building under analysis and room temperature variations are moderate.

Heat Balance Method

The heat balance method for calculating net space sensible loads is described in Chapter 18 and in the *ASHRAE Toolkit for Building Load Calculations* (Barnaby et al. 2005, 2009; Iu and Fisher 2004; Pedersen et al. 2001, 2003). Its development relies on the first law of thermodynamics (conservation of energy) at each surface. Because the heat balance method involves fewer assumptions than the weighting-factor method, it is more flexible and physically rigorous. However, the heat balance method requires more calculations at each point in the simulation process, using more computer time. This method has been validated in several studies (Chantrasrisalai et al. 2003a, 2003b; Eldridge et al. 2003; Iu et al. 2003).

The heat balance method allows the net instantaneous sensible heating and/or cooling load to be calculated on the space air mass. Generally, a heat balance equation is written for each enclosing surface, plus one equation for room air. Although not necessary, linearization is commonly used to simplify the radiative transfer formulation. This set of equations can then be solved for the unknown surface and air temperatures. Once these temperatures are known, they can be used to calculate the convective heat flow to or from the space air mass. The heat balance method is developed in Chapter 18 for use in design cooling load calculations.

The procedure described in Chapter 18 is aimed at obtaining the design cooling load for a ***fixed*** zone air temperature. For building energy analysis purposes, it is preferable to know the actual heat extraction rate. This may be determined by recasting Equation (27) of Chapter 18 so that the system heat transfer is determined simultaneously with the zone air temperature. The system heat transfer is the rate at which heat is transferred to the space by the system. Although this can be done by simultaneously modeling the zone and the system (Taylor et al. 1990, 1991), it is often convenient to make a simple, linearized representation of the system known as a *control profile*. This usually takes the form

$$q_{sys_j} = a + bt_{a_j} \tag{2}$$

where

q_{sys_j} = system heat transfer at time step j, W

a, b = coefficients that apply over a certain range of zone air temperatures

t_{a_j} = zone air temperature at time step j, °C

System heat transfer q_{sys_j} may be considered positive when heating is provided to the space and negative when cooling is provided.

Licensed for single user. © 2021, ASHRAE, Inc.

It is equal in magnitude but opposite in sign to the zone cooling load, as defined in Chapter 18, when zone air temperature is fixed.

Substituting Equation (2) into Equation (27) of Chapter 18 and solving for zone air temperature,

$$t_{a_j} = \frac{a + \sum_{i=1}^{N} A_i h_{ci} t_{si_{i,j}} + \rho c V_{infil_j} t_{o_j} + \rho c V_{vent_j} t_{v_j} + q_{c,int_j}}{-b + \sum_{i=1}^{N} A_i h_{ci} + \rho c V_{infil_j} + \rho c V_{vent_j}} \quad (3)$$

where

N = number of zone surfaces
A_i = area of ith surface, m^2
h_{ci} = convection coefficient for ith surface, $W/(m^2 \cdot K)$
$t_{si_{i,j}}$ = surface temperature for ith surface at time step j, °C
ρ = density, kg/m^3
c = specific heat of air, $J/(kg \cdot K)$
V = volumetric flow rate of air, m^3/s
t_{o_j} = outdoor air temperature at time step j, °C
t_{v_j} = ventilation air temperature at time step j, °C
q_{c,int_j} = sum of convective portions of all internal heat gains at time step j, W

The zone air heat balance equation [Equation (3)] must be solved simultaneously with the interior and exterior surface heat balance equations [Equations (26) and (25) in Chapter 18]. Also, the correct temperature range must be found to use the proper set of a and b coefficients; this may be done iteratively. Once the zone air temperature is found, the actual system heat transfer rate may be found directly from Equation (2).

Beyond treatment of system heat transfer, other considerations that may be important in building energy analysis programs include treatment of radiant cooling and heating systems, treatment of interzone heat transfer, modeling convection heat transfer, and modeling radiation heat transfer.

The heat balance method in Chapter 18 assumes the use of a single design day. In a building energy analysis program, it is most commonly used with a year's worth of design weather data. In this case, the first day of the year is usually simulated repeatedly until a steady-periodic response is obtained. Then, each day is simulated sequentially, and, where needed, historical data for surface temperatures and heat fluxes from the previous day are used.

When radiant cooling and heating systems are evaluated, the radiant source should be identified as a room surface. The calculation procedure considers the radiant source in the heat balance analysis. Therefore, the heat balance method is preferred over the weighting-factor method for evaluating radiant systems. Strand and Pedersen (1997) describe implementation of heat source conduction transfer functions that may be used for modeling radiant panels within a heat balance-based building simulation program.

In principle, this method extends directly to multiple spaces, with heat transfer between zones. In this case, some surface temperatures appear in the surface heat balance equations for two different zones. In practice, however, the size of the coefficient array required for solving the simultaneous equations becomes prohibitively large, and the solution time excessive. For this reason, some programs solve only one space at a time and assume that adjacent space temperatures are the same as the prior time step, or use iterative schemes to achieve a simultaneous solution. Other approaches may remove this limitation (Walton 1980).

Relatively simple exterior and interior convection models may be used for design cooling load calculation procedures. However, more sophisticated exterior convection models (Cooper and Tree 1973; Fracastoro et al. 1982; Melo and Hammond 1991; U.S. Department of Energy 1996-2016; Walton 1983; Yazdanian and Klems 1994) that incorporate the effects of wind speed, wind direction, surface orientation, etc., may be preferable. More detailed interior convection correlations for use in buildings are also available (Alamdari and Hammond 1982, 1983; Altmayer et al. 1983; Bauman et al. 1983; Bohn et al. 1984; Chandra and Kerestecioglu 1984; U.S. Department of Energy 1996-2016 Goldstein and Novoselac 2010; Khalifa and Marshall 1990; Peeters et al. 2011; Spitler et al. 1991; Walton 1983).

Also, more detailed models of exterior [e.g., Cole (1976); Walton (1983)] and interior [e.g., Carroll (1980); Davies (1988); Kamal and Novak (1991); Steinman et al. (1989); Walton (1980)] long-wave radiation transfer have been implemented in detailed building simulation programs.

Weighting-Factor Method

The weighting-factor method of calculating instantaneous space sensible load is a compromise between simpler methods (e.g., steady-state calculation) that ignore the ability of building mass to store energy, and more complex methods (e.g., complete energy balance calculations). With this method, space heat gains at constant space temperature are determined from a physical description of the building, ambient weather conditions, and internal load profiles. Along with the characteristics and availability of heating and cooling systems for the building, space heat gains are used to calculate air temperatures and heat extraction rates. This discussion is in terms of heat gains, cooling loads, and heat extraction rates. Heat losses, heating loads, and heat addition rates are merely different terms for the same quantities, depending on the direction of the heat flow.

The weighting factors represent Z-transfer functions (Kerrisk et al. 1981; York and Cappiello 1982). The Z-transform is a method for solving differential equations with discrete data. Two groups of weighting factors are used: heat gain and air temperature.

Heat gain weighting factors represent transfer functions that relate space cooling load to instantaneous heat gains. A set of weighting factors is calculated for each group of heat sources that differ significantly in the (1) relative amounts of energy appearing as convection to the air versus radiation, and (2) distribution of radiant energy intensities on different surfaces.

Air temperature weighting factors represent a transfer function that relates room air temperature to the net energy load of the room. Weighting factors for a particular heat source are determined by introducing a unit pulse of energy from that source into the room's network. The network is a set of equations that represents a heat balance for the room. At each time step, including the initial introduction, the energy flow to the room air represents the amount of the pulse that becomes a cooling load. Thus, a long sequence of cooling loads can be generated, from which weighting factors are calculated. Similarly, a unit pulse change in room air temperature can be used to produce a sequence of cooling loads.

A two-step process is used to determine the air temperature and heat extraction rate of a room or building zone for a given set of conditions. First, the room air temperature is assumed to be fixed at some reference value, usually the average air temperature expected for the room over the simulation period. Instantaneous heat gains are calculated based on this constant air temperature. Various types of heat gains are considered. Some, such as solar energy entering through windows or energy from lighting, people, or equipment, are independent of the reference temperature. Others, such as conduction through walls, depend directly on the reference temperature.

A space sensible cooling load for the room, defined as the rate at which energy must be removed from the room to maintain the reference value of the air temperature, is calculated for each type of instantaneous heat gain. The cooling load generally differs from the instantaneous heat gain because some energy from heat gain is

Licensed for single user. © 2021, ASHRAE, Inc.

absorbed by walls or furniture and stored for later release to the air. At time θ, the calculation uses present and past values of the instantaneous heat gain (q_θ, $q_{\theta-1}$), past values of the cooling load ($Q_{\theta-1}$, $Q_{\theta-2}$, ...), and the **heat gain weighting factors** (v_0, v_1, v_2, ..., w_1, w_2, ...) for the type of heat gain under consideration. Thus, for each type of heat gain q_θ, cooling load Q_θ is calculated as

$$Q_\theta = v_0 q_\theta + v_1 q_{\theta-1} + \cdots - w_1 Q_{\theta-1} - w_2 Q_{\theta-2} - \cdots \quad (4)$$

The heat gain weighting factors are a set of parameters that determine how much of the energy entering a room is stored and how rapidly stored energy is released later. Mathematically, the weighting factors are coefficients in a *Z*-transfer function relating the heat gain to the cooling load.

These weighting factors differ for different heat gain sources because the relative amounts of convective and radiative energy leaving various sources differ and because the distribution of radiative energy can differ. Heat gain weighting factors also differ for different rooms because room construction affects the amount of incoming energy stored by walls or furniture and the rate at which it is released. Sowell (1988) showed the effects of 14 zone design parameters on zone dynamic response. After the first step, cooling loads from various heat gains are added to give a total cooling load for the room.

In the second step, the total cooling load is used (with information on the room's HVAC system and a set of **air temperature weighting factors**) to calculate the actual heat extraction rate and air temperature. The actual heat extraction rate differs from the cooling load (1) because, in practice, air temperature can vary from the reference value used to calculate the cooling load, or (2) because of HVAC system characteristics. Deviation of air temperature t_θ from the reference value at hour θ is calculated as

$$t_\theta = 1/g_0 + [(Q_\theta - \mathrm{ER}_\theta) + P_1(Q_{\theta-1} - \mathrm{ER}_{\theta-1}) + P_2(Q_{\theta-2} - \mathrm{ER}_{\theta-2}) + \cdots - g_1 t_{\theta-1} - g_2 t_{\theta-2} - \cdots] \quad (5)$$

where ER_θ is the energy removal rate of the HVAC system at hour θ, and g_0, g_1, g_2, …, P_1, P_2, … are air temperature weighting factors, which incorporate information about the room, particularly thermal coupling between the air and the storage capacity of the building mass.

Example values of weighting factors for typical building rooms are presented in the following table. One of the three groups of weighting factors, for light, medium, and heavy construction rooms, can be used to approximate the behavior of any room. Some automated simulation techniques allow weighting factors to be calculated specifically for the building under consideration. This option improves the accuracy of the calculated results, particularly for a building with an unconventional design. McQuiston and Spitler (1992) provided electronic tables of weighting factors for a large number of parametrically defined zones.

Normalized Coefficients of Space Air Transfer Functions

Room Envelope Construction	g_0^*	g_1^*	g_2^*	P_0	P_1
	W/(m²·K)			Dimensionless	
Light	+9.54	–9.82	+0.28	1.0	–0.82
Medium	+10.28	–10.73	+0.45	1.0	–0.87
Heavy	+10.50	–11.07	+0.57	1.0	–0.93

Two assumptions are made in the weighting-factor method. First, the processes modeled are linear. This assumption is necessary because heat gains from various sources are calculated independently and summed to obtain the overall result (i.e., the superposition principle is used). Therefore, nonlinear processes such as radiation or natural convection must be approximated linearly. This assumption is not a significant limitation because these processes can be linearly approximated with sufficient accuracy for most calculations. The second assumption is that system properties influencing the weighting factors are constant (i.e., they are not functions of time). Often, a single set of weighting factors is used during the entire simulation period; however, multiple sets of weighting factors can be used to represent daily or seasonal variations. This assumption can limit the use of weighting factors in situations where important room properties vary more frequently during the calculation (e.g., the distribution of solar radiation incident on the interior walls of a room, which can vary over the day, and indoor surface heat transfer coefficients).

When the weighting-factor method is used, a combined radiative/ convective heat transfer coefficient is used as the indoor surface heat transfer coefficient. This value is assumed constant even though, in a real room, (1) radiant heat transferred from a surface depends on the temperature of other room surfaces (not on room air temperature) and (2) the combined heat transfer coefficient is not constant. Under these circumstances, an average value of the property must be used to determine the weighting factors. Cumali et al. (1979) investigated extensions to the weighting-factor method to eliminate this limitation.

Weighting factors are derived by introducing a unit pulse in a heat balance analysis. These analyses are performed relatively quickly as a preprocess step. Once the weighting factors are established, the simulation time can be significantly reduced, compared with performing a heat balance at every time step. There is an implicit trade-off between the limitations of the weighting-factor method and its improved computation speed compared with that of the heat balance method.

Comprehensive Room Transfer Function

The comprehensive room transfer function method (CRTF) is important as a reasonably accurate (comparable to weighting factor) model that is fast enough to be embedded in optimizations. One important application is model-predictive control. CRTF parameters may be estimated using forward (Seem et al. 1989) or inverse (Armstrong et al. 2006b; Gayeski et al. 2012) modeling. The interior terminating point of each wall is a common star node. Instead of separate surface flux and temperature for each wall, only the net star-node flux and temperature are evaluated. Exogenous radiant fluxes (solar and radiant shares of internal gains) are imposed on the star node as well. Radiant and convective exchange between walls also occurs through the star node. Convective heating and cooling by the system, on the other hand, as well as infiltration, ventilation, and the convective share of internal gains, enter the room model through its air node, which is coupled to the star node by a single, relatively small resistance. The resulting model has the topology of *n* conduction transfer functions terminating on a massless star node that is connected by a single resistance to an air capacitance node. However the *c* and *d* coefficients of all walls are combined, thus reducing the computational effort at each simulation time step. The CRTF thus has (up to the star node) the mathematical form of a multivariate autoregressive-moving-average with exogenous inputs (ARMAX) model. Methods of evaluating the common *c* and *d* coefficients and the star and air node resistances are described by Armstrong et al. (1992) and Seem et al. (1989).

Thermal-Network Methods

Although implementations of the thermal-network method vary, they all have in common the discretization of the building into a network of nodes connected by heat transfer paths. In many respects, thermal-network models may be considered a variant of the heat balance method. Thermal-network models can include an arbitrary number of nodes as required for the problem under consideration. For example, heat balance models generally use simple methods for distributing radiation from lights; thermal-network models may model the lamp, ballast, and luminaire housing separately.

Licensed for single user. © 2021, ASHRAE, Inc.

Thermal-network models depend on a heat balance at each node to determine node temperature and energy flow between all connected nodes. Energy flows may include conduction, convection, and short- or long-wave radiation. Methods have been developed that reduce the number of node interconnections (e.g., by replacing the general delta radiant exchange network with a star network) (Carroll 1980, 1981).

For any mode of energy flow, a range of finite-difference or finite-volume techniques may be used to model the energy flow between nodes. Taking transient conduction heat transfer as an example, the simplest thermal-network model would be a one- or two-capacitor resistance/capacitance network (Hammarsten 1987; Sonderegger 1977; Sowell 1990). Others have used more refined network discretization (Clarke 2001; Lewis and Alexander 1990; Walton 1993).

Advanced thermal-network models generally use a set of algebraic and differential equations. In most implementations, the solution procedure is separated from the models so that, in theory, different solvers might be used to perform the simulation. In contrast, in most heat balance and weighting factor programs the solution technique takes advantage of a constrained model structure. Various solution techniques have been used in conjunction with thermal-network models. Examples include graph theory combined with Newton-Raphson and predictor/corrector ordinary differential equation integration (Buhl et al. 1990) and the use of Euler explicit integration combined with sparse matrix techniques (Walton 1993).

Of the four sensible-load zone models discussed, thermal-network models are the most flexible and have the greatest potential for high accuracy. However, they also require the most computation time, and, in current implementations, require more user effort to take advantage of the flexibility.

3.2 ENVELOPE COMPONENT MODELING

Above-Grade Opaque Surfaces

Heat transfer through above-grade, opaque envelope components (e.g., walls, roofs, ceilings) is often approximated using transient one-dimensional (1D) calculations. This approximation is common to most building energy simulation tools. Two- and three-dimensional effects, such as thermal bridging, are often accounted for by adjusting the properties of the materials in a 1D construction. Chapter 25 discusses the calculation of heat transfer through opaque building surfaces, including the overall effective thermal transmittance (or U-factor) of a flat building assembly.

Thermal properties of building materials and other solids can be found in Chapter 26 (Table 1) and Chapter 33 (Table 3), respectively.

Transient 1D heat transfer is calculated for multilayered constructions using one of three methods:

- **Response factors** (Kusuda 1969). These factors relate the heat flux through the surface to temperature changes. The response factors are generated by calculating the response to a simple transient event (e.g., a step change) and observing the resulting changes in heat flux over time. Once obtained, response factors can be reused throughout a simulation to estimate the heat flux response to other transient temperature changes.
- **Conduction transfer functions (CTFs).** Similar to response factors, CTFs relate the current heat flux through a surface to the heat fluxes of previous time steps. CTFs are also generated by imposing a simple transient event and observing the resulting heat flux over time.
- **Direct numerical methods** (e.g., finite difference, finite element). These methods are required for nonlinear analysis such as for phase change materials and variable thermal properties.

Iu and Fisher (2004) provide an overview and comparison of response factors and CTFs.

Below-Grade Opaque Surfaces

Thermal modeling of building foundations (Claridge et al. 1993), including guidelines for placement of insulation, is described in Chapter 27 of this volume and Chapter 44 of the 2019 *ASHRAE Handbook—HVAC Applications*. Chapter 18 of this volume provides information for calculating transmission heat losses through slab foundations and through basement walls and floors. These calculations are appropriate for design loads but are not intended for estimating annual energy usage. This section provides information about calculation methods suitable for energy estimates over time periods of arbitrary length.

The magnitude of foundation heat transfer relative to other loads in the building depends on several factors, including the insulation design of the foundation and the shape and size of the foundation relative to the overall size of the building. Foundation heat losses (or gains) are more significant in buildings with lower foundation area-to-perimeter ratios (Bahnfleth and Pedersen 1990; Kruis 2015). Low area-to-perimeter ratios often coincide with small buildings (e.g., detached residential construction) and building footprints with narrow cross sections. Where higher ground-coupled floor area-to-perimeter ratios may occur (e.g., in warehouses, shopping malls, other low-rise commercial buildings), thermal mass effects related to the core-area (nonperimeter) portion of the ground-coupled floor may also be important.

Ground-coupled foundation heat transfer involves three-dimensional (3D) thermal conduction, moisture transport, and the long-time-constant heat storage properties of the ground. During the early 1990s, only simplified models could be routinely used for calculating ground heat transfer. These models were based on 1D steady-state conduction or 1D dynamic thermal diffusion modeling. Because of continuing increases in computing power, the state of the art in ground heat transfer modeling has improved. Several calculation methods have been developed and applied to building energy simulation software (Bahnfleth and Pedersen 1990; Beausoleil-Morrison 1996; Beausoleil-Morrison and Mitalas 1997; Clements 2004; ISO 1998). These methods are further described and compared to more detailed 3D numerical methods (Ben-Nakhi 2007; Crowley 2007; Deru 2003; Thornton 2007) as part of the IEA BESTEST ground-coupled heat transfer modeling test cases (Neymark et al. 2008).

Other examples of ground heat transfer modeling techniques applied to floors and basements are described in Andolsun et al. (2010), Krarti (1994a, 1994b), and Krarti and Chuangchid (1999), and a simplification of that method in Chapter 19 of the 2009 *ASHRAE Handbook—Fundamentals*, and in Krarti et al. (1988a, 1988b) and Winkelmann (2002).

Methods of estimating foundation heat transfer can be highly constrained simplifications to ease calculation requirements, or very detailed and computationally intensive. Although the state of the art in ground heat transfer modeling is improving, many whole-building simulation tools still rely on a loosely defined set of ground temperatures that are applied as an exterior boundary condition for a simplified 1D approximation. These temperatures are often based on lagged, monthly average outdoor dry-bulb temperatures. In reality, the temperature in the ground varies both spatially and temporally, and is heavily influenced by the presence of a conditioned building. Finding a balance between computation speed and numerical accuracy is the focus of the dissertation work performed by Kruis (2015). Kruis found that two-dimensional (2D) calculations capture much of the accuracy of the more detailed 3D methods with computation times reasonable for whole-building energy simulation tools.

Licensed for single user. © 2021, ASHRAE, Inc.

Fenestration

Fenestration systems (windows, skylights, and doors) affect building energy use through four basic mechanisms: (1) thermal heat transfer, (2) solar heat gain, (3) air leakage, and (4) daylighting. Details of each of these effects are covered in Chapter 15. Fenestration performance is characterized primarily by its overall coefficient of heat transfer (U-factor), solar heat gain coefficient (SHGC), and visible transmittance (VT). These metrics are typically used to rate fenestration products for a specific set of conditions that are not necessarily representative of the range of conditions encountered in a typical whole-building energy simulation.

The energy impact of fenestration systems depends on the thermal and spectral properties of each component, including

- Glazing substrates (panes)
- Glazing coatings
- Fill gas
- Opaque frame and divider
- Spacers between panes

Fenestration system models span a wide range of complexity and input requirements. Some of the simpler models apply a constant U-factor and SHGC to the system, whereas more advanced models may require finer details of the fenestration system that are not often available to energy modelers, such as

- Glazing reflectance (front and back) and transmittance at wavelengths spanning the solar, visible, and infrared spectrums, as well as at different angles of solar incidence
- Temperature-dependent thermal properties of fill gases
- Two-dimensional heat transfer through frames, dividers, and spacers

Many of these inputs can be found or generated in the suite of fenestration-related software tools developed by Lawrence Berkeley National Lab (LBNL 2016):

- WINDOW (for analyzing composite fenestration system thermal and optical properties)
- THERM (for analyzing two-dimensional heat transfer through building products)
- Optics (for analyzing optical properties of glazing systems)
- International Glazing Database (IGDB) (optical data for glazing products)

In most energy modeling applications, the level of detail required to compose a fenestration system using these software tools is not readily available. Instead, energy modelers are at most provided with the product's rated U-factor, SHGC, and VT, or specific values defined by compliance rules and incentive programs (e.g., ASHRAE *Standard* 90.1, ENERGY STAR®). With this use case in mind, Arasteh et al. (2009) developed an approach in EnergyPlus to represent fenestration systems with angle-dependent optical properties using only the rated U-factor, SHGC, and VT. This approach offers a higher level of accuracy than the assumption of constant values, but does not explicitly simulate the opaque frame and dividers components or the fill gas in the fenestration system.

Infiltration

Infiltration is defined as the flow of outdoor air via (1) leakage through unintentional openings (e.g., cracks, porosities) in the building envelope and (2) natural ventilation through exterior windows, doors, vents, etc. It is typically treated as an additional load for the purposes of whole-building energy modeling. The flow is driven by pressure differences and buoyancy forces, and may be counteracted by pressurizing the building or by sealing openings with air barriers, weatherstripping, and similar measures. Outdoor air that has entered a conditioned space will at some point need to be heated or cooled to maintain the space at the desired temperature. There are a number of procedures available for calculating infiltration and associated loads. Empirical models, based on the results of blower door tests, are most readily available for residential buildings because of more readily available measured data, such as effective leakage area and flow exponent. Models that treat the building as a single zone are most directly applicable to smaller buildings (e.g., houses). Models that treat buildings as a set of zones (not necessarily corresponding to thermal zones) are also available, but these models require parameters that may be difficult to determine without building-specific data. More information on these models and on the general issue can be found in Chapter 16. Discussion of natural ventilation modeling is included in this chapter's section on Low-Energy System Modeling. In the absence of the information necessary to use a more detailed approach, infiltration rates from appropriate standards or guideline documents (e.g., ASHRAE *Standard* 90.1; Gowri et al. 2009) can be used to determine the inputs for an energy model. For commercial buildings, which are typically designed to be pressurized, this approach may be more successful than for residential buildings, which may not be pressurized.

3.3 INPUTS TO THERMAL LOADS MODELS

Choosing Climate Data

Environmental data provide boundary conditions for many energy estimating and modeling methods. Many energy estimating and modeling methods require climate data from specific sources or in specific formats. The most common application is full-year hourly simulation using a typical meteorological year (TMY) to represent typical building operation. Other applications may require historical climate data (for model calibration), real-time climate data (for model predictive controls), or projected climate data (for predicting the impact of climate change on building energy consumption). Climate data are available from a growing number of sources. Chapter 14 discusses the use of climatic design information in greater detail and includes data for more than 8000 locations worldwide. Hensen and Lamberts (2011) list several other sources of climate data and discuss the requirements of climate data for various simulation applications.

Internal Heat Gains

Accurate representation of internal heat gains in building simulation is important for several reasons. These heat gains often compose a significant portion of HVAC system loads. In addition, heat sources such as lighting and office equipment may be significant direct contributors to building energy consumption.

Typical sources of internal heat gain represented in a simulation include occupants, lighting, and plug loads. Some buildings also include significant heat from cooking, refrigeration, laboratory, or manufacturing equipment.

The following simulation inputs are generally necessary to characterize a source of internal heat gain:

- **Peak heat rate.** For example, installed lighting power. Note that the actual peak heat rate for sources such as office equipment is often lower than the equipment's nameplate rating.
- **Time variation of heat rate.** The heat gain from most sources varies by hour and may vary by day of the week and by season.
- **Latent heat fraction.** Many sources of internal heat gain, such as lighting and most office equipment, produce only sensible heat. However, other sources, such as occupants and some cooking equipment, produce both sensible and latent heat. For those cases, the portion of the total heat gain entering the space as latent heat must be identified.
- **Radiant/convective split.** Sensible heat gain has two components: radiant and convective. The relative proportion between the

Licensed for single user. © 2021, ASHRAE, Inc.

two pathways affects the time delay between instantaneous heat gain and space load. Simulation programs often include default fractions for the split. Attention to these values is especially important when evaluating spaces with significant thermal mass.

- **Fraction of heat gain to space.** Not all of the heat produced by some sources of internal heat gain ends up directly in the space. In those cases, it may be necessary to specify the portion that goes to the space and the portion that goes elsewhere. One example is recessed lighting in a suspended ceiling: some of the energy consumed by the lights enters the space and the rest goes to the space above the ceiling. Another example is cooking equipment under a range hood: a portion of the heat enters the kitchen, primarily via radiation, and the rest of the heat goes to the exhaust air. The same concept applies to laboratory equipment in a fume hood or to industrial equipment where a portion of the heat output is captured by an exhaust system. Another example is a space using a displacement ventilation air delivery strategy: a portion of the heat gain from occupants and equipment in the occupied zone rises into the stratified zone or return air and does not end up as a load in the occupied zone.

Appropriate values for internal heat gain inputs may be different between energy calculations and HVAC system peak-load calculations. Although the basic form of input may be identical (e.g., both may require specifying office equipment power density), the objectives of the analyses are different. The typical objective of energy estimation is to determine likely energy consumption rather than worst-case energy consumption. Therefore, the appropriate values for internal heat gain inputs will typically be lower for energy estimation than for load calculations. ASHRAE research project RP-1093 developed different sets of diversity factors appropriate for energy calculations and for load calculations (Abushakra et al. 2000).

In many cases, information about actual internal heat gains is not available to the energy modeler, either because it is a new construction project and detailed equipment specifications are not available, or the project is an existing building and a detailed survey of heat sources is not practical. Therefore, it may be necessary to make assumptions. Chapter 18 provides valuable data on peak heat rates, radiant/convective splits, and fraction of heat to space for a range of equipment types. Other sources of internal gain assumptions include COMNET (2016), Building America simulation protocols (Wilson et al. 2014), and DOE reference buildings (Deru et al. 2011).

Occupant Behavior

Technologies alone do not necessarily guarantee low energy use in buildings. Occupant behavior has a significant effect on building performance. Occupants' expectations of satisfaction with their indoor environment drive various actions, such as adjusting thermostat settings, opening windows, turning on lights, closing window blinds, consuming domestic hot water, and moving around, to satisfy their physical and nonphysical needs. These actions affect the built environment and energy use. Clearly understanding and accurately modeling occupant behavior in buildings is crucial to reducing the gap between design and actual building energy performance (Gunay et al. 2013; Hoes et al. 2009; Turner and Frankel 2008; Yan et al. 2015), especially for low-energy buildings relying more on passive design features, occupancy-controlled technologies, and occupant engagement.

Occupant behavior is represented in predefined deterministic schedules or fixed settings to describe occupant movement and activities, the use of lighting, plug loads, and HVAC system operation. Assumptions of occupant input can be found in ASHRAE publications (e.g., Handbook, standards, guidelines), DOE reference buildings, simulation guides (COMNET 2016), building design documents, or measured data from existing buildings. Abushakra and Claridge (2008) developed a method for modeling occupancy in commercial buildings based on monitored lighting and receptacles energy use. The method provides typical occupancy load shapes that can be used in both forward building energy simulations and data-driven models. When these static schedules and settings are entered into building energy modeling (BEM) programs, the results are deterministic and homogeneous, ignoring the stochastic nature, dynamics, and diversity of occupant behavior. For example, occupants can open windows for various reasons: (1) feeling hot (thermal comfort driven), (2) feeling stuffy (indoor air quality driven), (3) arriving in a space (event driven), and (4) personal habit.

Alternative approaches used to integrate occupant behavior into models include embedded behavior modules adopted by BEM programs or agent-based modeling approaches that specify how agents (in this case, occupants) interact with one another and with their environment. Integration of occupant behavior with BEM programs ranges from built-in user functions to more flexible cosimulation. The user functions approach allows users, to a certain degree of flexibility, to write custom code to implement new or overwrite existing default building operation and supervisory controls. The cosimulation approach allows separate behavior tools to run simultaneously and exchange occupant information in a collaborative manner with BEM programs (Hong et al. 2016a; Wetter et al. 2011). Agent-based modeling specifies occupant attributes, behavioral rules, memory, resources, decision-making sophistication, and procedures for modifying current behavioral rules. Andrews et al. (2011), Langevin (2014), and Robinson (2011) developed agent-based modeling tools for cosimulation.

Despite advancements, there are significant and fundamental scientific problems remaining to be addressed in modeling occupant behavior, including (1) choosing the best modeling approach based on available data and for a particular application, (2) standardizing the representation of occupant behavior for interoperability (Hong et al. 2015), (3) selecting methods to evaluate occupant behavior models, (4) interpreting the simulation results from the use of stochastic models, and (5) considering social and behavioral influencing factors. IEA EBC (2013-2017) Annex 66 addresses some of these problems and provides a literature database on occupant behavior research.

Thermal Zoning Strategies

Configuration of thermal zones for building energy simulation commonly follows the core and perimeter zone method (Hirsch 2003; LBNL 1984.). The core and perimeter approach divides a building into an approximate perimeter of thermal zones within 4.5 to 6 m from the exterior walls and then further divides the building into separate perimeter zones for each orientation.

A commonly used thermal zoning guideline is provided in ASHRAE *Standard* 90.1, Appendix G, which describes the standard's performance rating method. The standard allows combining two or more actual thermal zones into a single zone if they have the same space usage, their exterior glazed surfaces have the same orientation (within 45°), and they are served by the same type of HVAC system.

In certain cases, spaces that have similar thermal conditions may be aggregated into fewer zones within a simulation model with only a minor difference in simulation outcome, as stated in Lokmanhekim (1971), who proposed a method to define thermal zones by grouping spaces based on comparison of load profile plots.

Several recent studies have considered different approaches for thermal zoning:

- Raftery (2011) developed a method that defines the various type of thermal zones in a simulation based on four major criteria: (1) function of the space, (2) position of the zone relative to the exterior, (3) available measured data, and (4) method used to

Licensed for single user. © 2021, ASHRAE, Inc.

condition the zone. Raftery's method yields a more detailed thermal zoning plan than the traditional core and perimeter zoning method. However, the method is not automated, relying instead on a user's subjective inputs to a simulation program.

- Georgescu et al. (2012) developed a method that analyzes a detailed building energy model using an optimization method to develop zoning approximations based on observations of zone temperature. However, in this method, a detailed model of all zones must first be created to establish a baseline simulation for comparison; this can take a significant amount of time and can introduce uncertainty as the number of parameters in the model increases. Like Raftery (2011), the Georgescu et al. (2015) method also lacks an automated procedure.
- Yi (2015) developed a user interface that suggests optimized thermal-zone layouts based on space arrangement. However, Yi's method is based only on the spatial functions and does not consider varying internal load, space use, or system type. This method relies on the user's judgment to perform the final selection of zones.
- Dogan et al. (2015) present an algorithm to automatically convert arbitrary building massing models into multiple-zone building energy models. The applications include model generation during schematic design and generation of models for urban massing studies.

Although these efforts provide promising steps toward improved thermal zoning for building energy simulation, a truly automated, one-size-fits-all approach remains to be developed.

4. HVAC COMPONENT MODELING

4.1 MODELING STRATEGIES

The performance of HVAC components varies based on component design, operating conditions, and control strategies. Two different strategies are commonly used to represent the performance of HVAC components: empirical (regression-based) models and first-principles models.

Empirical (Regression-Based) Models

Although some secondary components (e.g., heat exchangers, valves) are readily described by fundamental engineering principles, the complex nature of some equipment (e.g., chillers, boilers, fans coupled with air distribution systems) has discouraged the use of first-principles models for energy calculations in favor of regression-based component models based on manufacturers' empirical performance data.

Energy consumption of complex equipment generally depends on equipment design, load conditions, environmental conditions, and equipment control strategies. For example, chiller performance depends on the basic equipment design features (e.g., heat exchange surfaces, compressor design), temperatures and flow through the condenser and evaporator, and methods for controlling the chiller at different loads and operating conditions (e.g., inlet guide vane control or variable-speed compressor control on centrifugal chillers to maintain leaving chilled-water temperature set point). In general, these variables vary constantly and require calculations on an hourly or subhourly basis.

Energy consumption characteristics of primary equipment have traditionally been modeled using equations developed by regression analysis of manufacturers' published design data. Historically, published data were available only for full-load design conditions, and additional correction functions were used to correct the full-load data to part-load conditions. However, industry efforts to standardize reporting of performance data over a range of operating conditions (proposed ASHRAE *Standard* 205P) are making it possible to capture the performance of specific equipment via automated performance maps or custom regression fits. Use of such standard-format data is expected to become the preferred approach for transmitting equipment performance characteristics to energy modeling software.

The functional form of the regression equations and correction functions takes many forms, including exponentials, Fourier series, and, most commonly, second- or third-order polynomials. Selection of an appropriate functional form depends on the behavior of the equipment. In some cases, energy consumption is calculated using direct interpolation from data tables.

A typical approach to modeling primary equipment in energy simulation programs is to assume the following functional form for equipment power consumption:

$$\begin{aligned} P &= \text{PIR} \times \text{Load} \\ \text{PIR} &= \text{PIR}_{nom} f_1(t_a, t_b, \ldots) f_2(\text{PLR}) \end{aligned} \tag{6}$$

$$\begin{aligned} C_{avail} &= C_{nom} f_3(t_a, t_b, \ldots) \\ \text{PLR} &= \frac{\text{Load}}{C_{avail}} \end{aligned} \tag{7}$$

where

P = equipment power, kW
PIR = power input ratio
PIR_{nom} = power input ratio under nominal full-load conditions
Load = power delivered to load, kW
C_{avail} = available equipment capacity, kW
C_{nom} = nominal equipment capacity, kW
f_1 = function relating full-load power at off-design conditions (t_a, t_b, …) to full-load power at design conditions
f_2 = fraction full-load power function, relating part-load power to full-load power
f_3 = function relating available capacity at off-design conditions (t_a, t_b, …) to nominal capacity
t_a, t_b = various operating temperatures that affect power
PLR = part-load ratio

The part-load ratio is the ratio of the load to the available equipment capacity at given off-design operating conditions. Like the power, the available, or full-load, capacity is a function of operating conditions.

The particular forms of off-design functions f_1 and f_3 depend on the specific type of equipment. For example, for fossil-fuel boilers, full-load capacity and power (or fuel use) can be affected by thermal losses to ambient temperature. However, these off-design functions are typically considered to be unity in most building simulation programs. For condensing boilers, efficiency is significantly affected by boiler entering water temperature, which is therefore an important input for the f_1 function (see also the section on Boilers). For chillers, both capacity and power are affected by condenser and evaporator temperatures, which are often characterized in terms of their secondary fluids. For direct-expansion air-cooled chillers, operating temperatures are typically the wet-bulb temperature of air entering the evaporator and the dry-bulb temperature of air entering the condenser. For liquid chillers, the temperatures are usually the leaving chilled-water temperature and the entering condenser water temperature (see also the section on Chillers). For fans and pumps, energy consumption is often represented as a polynomial function of airflow or fluid flow, as described in the section on Fans, Pumps, and Distribution Systems.

As an example, consider the cooling performance of a direct-expansion (DX) packaged single-zone rooftop unit. The nominal rated performance of these units is typically given for an outdoor air temperature of 35°C and evaporator entering coil conditions of 26.7°C db and 19.4°C wb. However, performance changes as

Table 3 Correlation Coefficients for Off-Design Relationships

Corr.	0	1	2	3	4	5
f_1	–1.063931	0.0306584	0.0001269	0.0154213	0.0000497	0.0002096
f_3	0.8740302	0.0011416	0.0001711	–0.002957	0.0000102	0.0000592

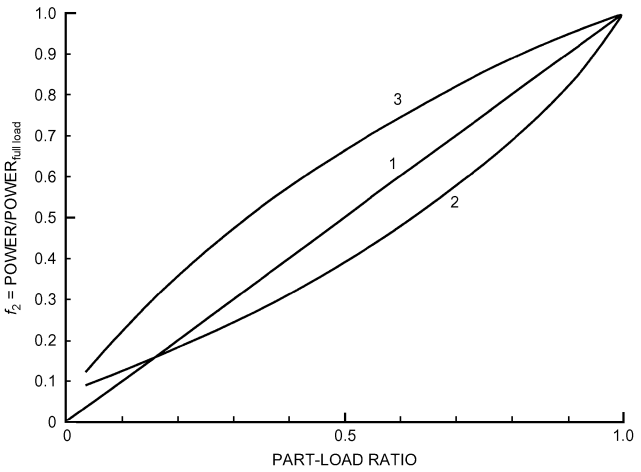

Fig. 5 Possible Part-Load Power Curves

outdoor temperature and entering coil conditions vary. To account for these effects, the DOE-2.1E simulation program expresses the off-design functions f_1 and f_3 with biquadratic functions of the outdoor dry-bulb temperature and the coil entering wet-bulb temperature. Many other programs use similar functions.

$$f_1(t_{wb,ent}, t_{oa}) = a_0 + a_1 t_{wb,ent} + a_2 t_{wb,ent}^2 + a_3 t_{oa} + a_4 t_{oa}^2 + a_5 t_{wb,ent} t_{oa} \quad (8)$$

$$f_3(t_{wb,ent}, t_{oa}) = c_0 + c_1 t_{wb,ent} + c_2 t_{wb,ent}^2 + c_3 t_{oa} + c_4 t_{oa}^2 + c_5 t_{wb,ent} t_{oa} \quad (9)$$

The constants in Equations (8) and (9) are given in Table 3.

The fraction full-load power function f_2 represents the change in equipment efficiency at part-load conditions and depends heavily on the control strategies used to match load and capacity. Figure 5 shows several possible shapes of these functional relationships. Curve 1 represents equipment with constant efficiency, independent of load. Curve 2 represents equipment that is most efficient in the middle of its operating range. Curve 3 represents equipment that is most efficient at full load. Note that these types of curves apply to both boilers and chillers.

First-Principles Models

Engineering first principles such as thermodynamics as well as heat, mass, and momentum transfer can be used to develop models of primary equipment as well as secondary components. Gordon and Ng (1994, 1995), Gordon et al. (1995), Jiang and Reddy (2003), Lebrun et al. (1999), and others have sought to develop such models in which unknown model parameters are extracted from measured or published manufacturers' data.

The energy analyst often must choose the appropriate model for the job. For example, a complex boiler model is not appropriate if the boiler operates at virtually constant efficiency. Similarly, a regression-based model might be appropriate when the user has a full dataset of reliable in-situ measurements of the plant. A regression-based model may also be a good choice when manufacturer performance data is provided for a full range of anticipated operating conditions. However, first-principles physical models generally have several advantages over pure regression models:

- Physical models allow confident extrapolation outside the range of available data.
- Regression is still required to obtain values for unknown physical parameters. However, the values of these parameters usually have physical significance, which can be used to estimate default parameter values, diagnose errors in data analysis through checks for realistic parameter values, and even evaluate potential performance improvements.
- The number of unknown parameters is generally much smaller than the number of unknown coefficients in the typical regression model. For example, the standard ARI compressor model requires as many as 30 coefficients, 10 each for regressions of capacity, power, and refrigerant flow. By comparison, a physical compressor model may have as few as four or five unknown parameters. Thus, physical models require fewer measured data.
- Data on part-load operation of chillers and boilers have been notoriously difficult to obtain but are becoming more readily available from manufacturers. Part-load corrections often represent the greatest uncertainty in the regression models, while causing the greatest effect on annual energy predictions. By comparison, physical models of full-load operation often allow direct extension to part-load operation with little additional required data.

Physical models of primary HVAC equipment can be found in many HVAC textbooks, but some of the models described here are specifically based on the work of Bourdouxhe et al. (1994a, 1994b, 1994c) in developing the ASHRAE *HVAC 1 Toolkit* (Lebrun et al. 1999). Each elementary component's behavior is characterized by a limited number of physical parameters, such as heat exchanger heat transfer area or centrifugal compressor impeller blade angle. Values of these parameters are identified, or tuned, based on regression fits of overall performance compared to measured or published data.

Although physical models are based on physical characteristics, values obtained through a regression analysis of manufacturers' data are not necessarily representative of the actual measured values. Strictly speaking, the parameter values are regression coefficients with estimated values, identified to minimize the error in overall system performance. In other words, errors in the fundamental models of equipment are offset by over- or underestimation of the parameter values.

4.2 TERMINAL COMPONENTS

Terminal Units and Controls

Although many terminal units do not directly consume energy, they often have a significant effect on the energy consumed by primary and secondary equipment. For example, the minimum airflow set point for a variable-air-volume (VAV) terminal unit with a reheat coil affects supply fan energy, cooling energy consumption of the chiller or direct-expansion compressor, heating energy consumption of the electric reheat coil or central plant boiler, and pump energy for delivery of chilled and hot water. Therefore, the representation of terminal units in energy-estimating programs deserves special attention.

Several types of terminal units are commonly represented in energy-estimating programs: single-duct VAV boxes with and

Licensed for single user. © 2021, ASHRAE, Inc.

without reheat coils, single-duct VAV boxes with parallel or series induction fans, dual-duct VAV boxes, chilled-beam induction units, fan-coils, radiant panels, baseboard radiators, and others. Chapters 4, 5, and 20 of the 2020 *ASHRAE Handbook—HVAC Systems and Equipment* provide a description of many types of terminal units and their operation.

When selecting an energy-estimating program, it is important to note that not all programs explicitly represent some of these types of terminal units or they may not directly represent the desired control scheme.

The following considerations regarding accuracy and energy consumption are important when representing terminal units in energy-estimating programs:

- **VAV box minimum airflow set point.** As noted previously, this setting has a significant impact on energy consumption in a VAV system, and using default inputs may lead to inaccurate model results. In some actual systems, the minimum airflow set point is varied over time in a demand-controlled ventilation scheme, and in those cases it is important to ensure that the selected energy-estimating program can represent that strategy.
- **VAV box damper control in heating mode.** In actual systems, VAV box airflow in heating mode may remain at a fixed minimum position or may modulate to provide increased airflow as heating load increases, typically using a specific heating maximum airflow set point that may be different from the maximum cooling airflow. This later strategy is often called reverse-acting damper control (dual-maximum), and it can lead to reduced reheat energy. Many energy-estimating programs can represent both control strategies, and this is an important input to verify.
- **Fan power for VAV boxes with induction fans.** In some cases, these small induction fans are relatively inefficient, and this is an important input to verify.
- **Control of parallel induction fans in VAV boxes.** Typically, in a parallel induction VAV box, the fan runs only in heating mode. To accurately represent this fan operation, it is important to verify in the energy-estimating program how the control for this fan is specified.
- **Chilled-water temperature limits for chilled-beam systems.** In a typical chilled beam design, there is a minimum setpoint for entering water temperature to avoid condensation on the coils. This set point is higher than that for a typical chilled-water distribution system, and it may affect the efficiency of the chilled-water system and the pumping energy.
- **Temperature input requirements for radiant heating systems and radiators.** Different types of radiant heating terminal units have different hot-water temperature input requirements. The corresponding hot-water supply and return temperature requirements on the boilers will affect boiler operating efficiency, especially for condensing boilers.

Underfloor Air Distribution

Underfloor air distribution (UFAD) is sometimes considered as an energy-efficient HVAC strategy, and a method to estimate its energy performance is a valuable design tool. UFAD systems offer potential for energy savings in several ways. These systems typically operate at higher cooling supply air temperatures compared to overhead air delivery systems, and offer potential for additional economizer energy savings. Primary cooling equipment efficiency may improve when providing higher-temperature supply air. In addition, if the UFAD system is operated to maintain partially mixed air distribution, as described in Chapter 57 of the 2019 *ASHRAE Handbook—HVAC Applications*, then the zone air distribution effectiveness may be better than that of an overhead air delivery system and allow a reduction in outdoor air ventilation rate.

A limitation of many energy-estimating programs is the assumption that air within thermal zones is fully mixed, and these programs cannot directly represent the performance of a UFAD system that is operated to create some temperature stratification. Approximate methods have been used by energy modelers, such as raising the thermostat set point in the UFAD zones to represent a higher average air temperature or representing the actual zone with two stacked zones in the model. See Energy Design Resources (2012) for more information.

A method for explicit modeling of UFAD systems has been developed for the EnergyPlus program, with separate models for interior and perimeter zones (Webster et al. 2013).

Thermal Displacement Ventilation

Thermal displacement ventilation (TDV) is another air delivery strategy that offers energy efficiency benefits. A displacement system is typically designed to achieve fully stratified air distribution, as described in Chapter 57 of the 2019 *ASHRAE Handbook—HVAC Applications*. The potential efficiency benefits are similar to UFAD systems.

Modelers seeking to estimate the energy performance of a TDV system face the same basic limitations as with UFAD systems, and similar approximations have been used in practice. However, a method for modeling TDV represented by three nodes (floor temperature, occupied-zone temperature, and upper-zone temperature) is implemented in EnergyPlus (U.S. Department of Energy 1996-2016).

Radiant Heating and Cooling Systems

Heating and cooling a space using heated and cooled panels is fundamentally different from using conditioned air. In a radiant system, a significant fraction of the sensible heating and cooling occurs by radiant heat transfer between the radiant panel and the surfaces in the space. This process is described in Chapter 6 of the 2020 *ASHRAE Handbook—HVAC Systems and Equipment*.

As noted in the Heat Balance Method section, energy-estimating programs that use the heat balance method for space load calculations are generally preferred for representing the performance of radiant systems. Use of the heat balance method allows accounting for radiant heat transfer among surfaces in a space, and a heated or cooled panel may be represented as one of those surfaces.

4.3 SECONDARY SYSTEM COMPONENTS

Secondary HVAC systems generally include all elements of the overall building energy system between a central heating and cooling plant and the building terminal units and zones. The precise definition depends heavily on the building design. A secondary system typically includes air-handling equipment; air distribution systems with associated ductwork; dampers; fans; and heating, cooling, and humidity-conditioning equipment. They also include liquid distribution systems between the central plant and the zone and air-handling equipment, including piping, valves, and pumps.

Although the exact design of secondary systems varies dramatically among buildings, they are composed of a relatively small set of generic HVAC components, including distribution components (e.g., pumps/fans, pipes/ducts, valves/dampers, headers/plenums, fittings) and heat and mass transfer components (e.g., heating coils, cooling and dehumidifying coils, liquid heat exchangers, air heat exchangers, evaporative coolers, steam injectors and other humidifiers). Most secondary systems can be described by simply connecting these components to form the complete system.

Energy estimation through computer simulation sometimes mimics the modular construction of secondary systems by using modular

Licensed for single user. © 2021, ASHRAE, Inc.

simulation elements [e.g., the ASHRAE *HVAC2 Toolkit* (Brandemuehl 1993; Brandemuehl and Gabel 1994), the simulation program TRNSYS (Klein et al. 1994; TRNSYS 2012), and Annex 10 activities of the International Energy Agency (IEA ECBCS 1987)]. To the extent that the secondary system consumes energy and transfers energy between the building and central plant, an energy analysis can be performed by characterizing the energy consumption of the individual components and the energy transferred among system components.

In many energy-estimating programs, secondary systems are represented by a mix of component models and simplified system models. For example, it is common for air and hydronic distribution systems to be represented by energy models that do not explicitly include components such as pipes/ducts, coils, and valves/dampers. Those methods are described in the following section.

In this chapter, secondary components are divided into two categories: (1) distribution components and (2) heat and mass transfer components.

Fans, Pumps, and Distribution Systems

The distribution system of an HVAC system affects energy consumption in two ways. First, fans and pumps consume electrical energy directly, based on the flow and pressures under which a device operates. Ducts and dampers, or pipes and valves, and the system control strategies affect flow and pressure at each fan or pump. Second, thermal energy is often transferred to (or from) the fluid by (1) heat transfer through pipes and ducts and (2) electrical input to fans and pumps. Analysis of system components should, therefore, account for both direct electrical energy consumption and thermal energy transfer.

Fan and pump performance are discussed in Chapters 21 and 44 of the 2020 *ASHRAE Handbook—HVAC Systems and Equipment*. In addition, Chapter 21 of this volume covers pressure loss calculations for airflow in ducts and duct fittings, and the effects of system air leakage. Chapter 22 presents a similar discussion for fluid flow in pipes. Although these chapters do not specifically focus on energy estimation, energy use is governed by the same performance characteristics and engineering relationships. Strictly speaking, performance calculations for a building's fan and air distribution system require a detailed pressure balance on the entire network. For example, in an air distribution system, airflow through the fan depends on its physical characteristics, operating speed, and pressure differential across the fan. Pressure drop through the air distribution system depends on duct construction (i.e., friction and fitting losses), coil and filter characteristics, damper positions, air leakage, and airflow through each component. Interaction between the fan and air distribution system results in a set of coupled, nonlinear algebraic equations. Models and subroutines for performing these calculations are available in the ASHRAE *HVAC2 Toolkit* (Brandemuehl 1993) and CONTAM (NIST 2000-2016). A simplified, physics-based model of the system curve, which represents the system pressure drop as seen by the fan, is described by Sherman and Wray (2010).

Detailed analysis of a distribution system requires flow and pressure balancing among the components, but nearly all commercially available energy analysis methods approximate the effect of the interactions with part-load performance curves [empirical (regression-based) component models]. This approach eliminates the need to calculate pressure drop through the distribution system at off-design conditions. Two simplified methods are described in the following sections.

Polynomial Curve Fit. Part-load curves are often expressed in terms of a **power input ratio** as a function of the part-load ratio, defined as the ratio of part-load flow to design flow:

$$\text{PIR} = \frac{W}{W_{full}} = f_{plr}\left(\frac{Q}{Q_{full}}\right) \tag{10}$$

where

PIR = power input ratio
W = fan motor input power at part load, W
W_{full} = fan motor input power at full load or design, W
Q = fan airflow rate at part load, m^3/s
Q_{full} = fan airflow rate at full load or design, m^3/s
f_{plr} = regression function, typically polynomial or power law

The exact shape of the part-load curve depends on the effect of flow control on the pressure and fan efficiency and may be calculated using a detailed analysis or measured field data. Figure 6 shows the relationship for three typical fan control strategies, as represented in a simulation program (York and Cappiello 1982). In the simulation program, the curves are represented by polynomial regression equations. Models and subroutines for performing these calculations are also available in the ASHRAE *HVAC2 Toolkit* (Brandemuehl 1993).

Figure 7 shows an example of a similar curve for the part-load operation of a fan system in a monitored building (Brandemuehl and Bradford 1999). In this case, the fan system represents 10 separate air handlers, each with supply and return fans, operating with variable-speed fan control to maintain a set duct static pressure.

Component Model. A second method can be used for fan system energy estimation in variable-airflow systems. It accounts

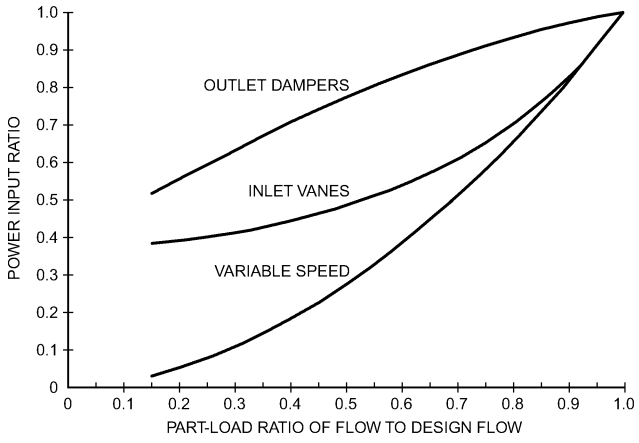

Fig. 6 Part-Load Curves for Typical Fan Operating Strategies
(York and Cappiello 1982)

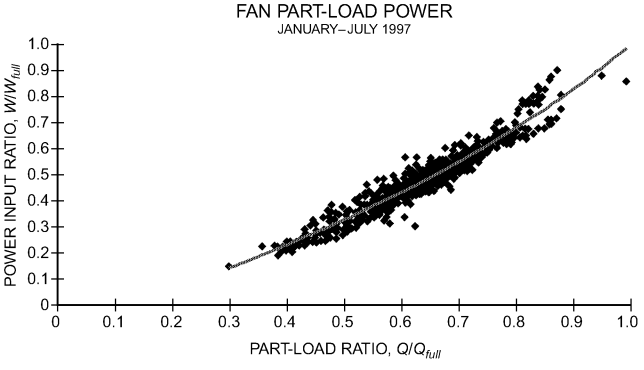

Fig. 7 Fan Part-Load Curve Obtained from Measured Field Data under ASHRAE RP-823
(Brandemuehl and Bradford 1999)

Licensed for single user. © 2021, ASHRAE, Inc.

separately for the substantial part-load performance variations that can occur for the fans, fan drive belts, fan motor, and variable-frequency drives (VFDs). For fans, dimensionless models are used to represent fan efficiency and speed variations with airflow. This method also uses a physics-based model (often called the "system curve") for determining flow-dependent fan pressure rise (Sherman and Wray 2010). Note that system curves with duct static pressure controls or significant pressure drops through coils and filters do not follow the commonly assumed quadratic system curve. Fan power is calculated using airflow, pressure rise, and fan efficiency at each time step. Calculating fan power and speed allows determining fan shaft torque and the resulting loads on drive components (belts, motors, and VFDs). Note that fan laws do not apply to drive components. In the absence of physics-based models, regression models based on available data can be used to represent belt, motor, and VFD part-load efficiency variations. An implementation of this approach, developed by Wray in 2010, is included in EnergyPlus, and details are provided in the *EnergyPlus Engineering Reference* (U.S. Department of Energy 1996-2016).

A benefit of this approach is its ability to directly represent the impacts of low-pressure-drop distribution systems, air leakage reduction, and duct static-pressure reset control, which are important efficiency strategies for many systems. This approach can also represent the effects of fan system component oversizing and changes for components such as fans, belts, motors, and variable-frequency drives.

A disadvantage to the component model is that the additional capabilities require additional inputs. However, generic values for model parameters are provided in the EnergyPlus documentation.

Fan and Pump Heat. Heat dissipated to the airstream by fan operation increases airstream temperature. Fan shaft power is usually assumed to be dissipated fully in the airstream. Motor losses also contribute if the motor is mounted in the airstream. For pumps, these contributions are typically assumed to be zero because the motor is not mounted in the water stream, and the ratio of transport power to thermal capacitance rate is usually much less for water than for air.

The following equation provides a convenient and general model to calculate the heat transferred to the fluid by a motor:

$$q_{fluid} = [\eta_m + (1 - \eta_m) f_{m,\,loss}]W \quad (11)$$

where

q_{fluid} = heat transferred to fluid, W
$f_{m,loss}$ = fraction of motor heat loss transferred to fluid stream, dimensionless (= 1 if fan mounted in airstream, = 0 if fan mounted outdoor airstream)
W = fan motor input power, W
η_m = motor efficiency

The heat rejected by VFDs and the fraction of motor heat not transferred to the airstream should be accounted for as building loads.

Heat and Mass Transfer Components

Secondary HVAC systems comprise heat and mass transfer components (e.g., steam or hot-water air-heating coils, chilled-water cooling and dehumidifying coils, shell-and-tube liquid heat exchangers, air-to-air heat exchangers, evaporative coolers, steam injectors). Although these components do not consume energy directly, their thermal performance dictates interactions between building loads and energy-consuming primary components (e.g., chillers, boilers). In particular, secondary component performance determines the entering fluid conditions for primary components, which in turn determine energy efficiencies of primary equipment. In addition, heat and mass transfer components may affect air and fluid flow, which affect performance of energy-consuming secondary components such as fans and pumps. Accurate energy calculations cannot be performed without appropriate models of the system heat and mass transfer components.

For example, load on a chiller is typically described as the sum of zone sensible and latent loads, plus any heat gain from ducts, plenums, fans, pumps, and piping. However, the chiller's energy consumption is determined not only by the load but also by the return chilled-water temperature and flow rate. The return water condition is determined by cooling coil performance and part-load operating strategy of the air and water distribution system. The cooling coil might typically be controlled to maintain a constant leaving air temperature by modulating water flow through the coil. In such a scenario, the cooling coil model must be able to calculate the leaving air humidity, water temperature, and water flow rate given the cooling coil design characteristics and entering air temperature and humidity, airflow, and water temperature.

Virtually all building energy simulation programs include, and require, models of heat and mass transfer components. These models are generally relatively simple. Whereas a coil designer might use a detailed tube-by-tube analysis of conduction and convection heat transfer and condensation on fin surfaces to develop an optimal combination of fin and tube geometry, an energy analyst is more interested in determining changes in leaving fluid states as operating conditions vary during the year. In addition, the energy analyst is likely to have limited design data on the equipment and, therefore, requires a model with very few parameters that depend on equipment geometry and detailed design characteristics.

A typical approach to modeling heat and mass transfer components for energy calculations is based on an **effectiveness-NTU heat exchanger model** (Kays and London 1984). The effectiveness-NTU (number of transfer units) model is described in most heat transfer textbooks and briefly discussed in Chapter 4. It is particularly appropriate for describing leaving fluid conditions when entering fluid conditions and equipment design characteristics are known. Also, this model requires only a single parameter to describe the characteristics of the exchanger: the overall transfer coefficient UA, which can be determined from limited design performance data.

Effectiveness methods are used to perform energy calculations for a variety of sensible heat exchangers in HVAC systems. For typical finned-tube air-heating coils, the cross-flow configuration with both fluid streams unmixed is most appropriate. Air-to-air heat exchangers may be cross- or counterflow. For liquid-to-liquid exchangers, tube-in-tube equipment can be modeled as parallel or counterflow, depending on flow directions; correlations for shell-and-tube effectiveness and NTU, which depend on the extent of baffling and the number of tube passes, are given in heat transfer texts (Mills 1999).

The energy analyst must determine the UA to describe the operations of a specific heat exchanger. There are three ways to determine this important parameter: direct calculation, measurement, and manufacturers' data. Given detailed information about the materials, geometry, and construction of the heat exchanger, fundamental heat transfer principles can be applied to calculate the overall heat transfer coefficient. However, the method most appropriate for energy estimation is use of manufacturers' performance data or measurement of installed performance. In reporting the design performance of a heat exchanger, a manufacturer typically gives the heat transfer rate under various operating conditions, with operating conditions described in terms of entering fluid flow rates and temperatures. The effectiveness and UA can be calculated from the given heat transfer rate and entering fluid conditions.

Example 3. An energy analyst seeks to evaluate a hot-water heating system that includes a hot-water heating coil. The energy analysis program uses an effectiveness-NTU model of the coil and requires the UA of the coil as an input parameter. Although detailed information on the coil geometry and heat transfer surfaces is not available, the manufacturer

Licensed for single user. © 2021, ASHRAE, Inc.

states that the one-row hot-water heating coil delivers 240 kW of heat under the following design conditions:

Design Performance

Entering water temperature t_{hi} = 80°C
Water mass flow rate $\dot{m}_h$ = 5.0 kg/s
Entering air temperature t_{ci} = 20°C
Air mass flow rate $\dot{m}_c$ = 8.0 kg/s
Design heat transfer q = 240 kW

Solution: First determine the heat exchanger *UA* from design data, then use *UA* to predict performance at off-design conditions. Effectiveness-NTU relationships are used for both steps. The key assumption is that the *UA* is constant for both operating conditions.

a) An examination of flow rates and fluid specific heats allows calculation of the hot-fluid capacity rate C_h and the cold-fluid capacity rate C_c at design conditions, and the capacity rate ratio Z.

$$C_h = (\dot{m}c_p)_h = (5.0)(4.195) = 20.97 \text{ kW/K}$$

$$C_c = (\dot{m}c_p)_c = (8.0)(1.007) = 8.05 \text{ kW/K}$$

$$C_{max} = C_h \qquad C_{min} = C_c$$

$$Z = \frac{C_{min}}{C_{max}} = 0.384$$

where c_p is specific heat and c_{max} and c_{min} are the larger and smaller of the capacity rates, respectively,

b) Effectiveness can be directly calculated from the heat transfer definition.

$$\varepsilon = \frac{(t_{co} - t_{ci})}{(t_{hi} - t_{ci})} = \frac{q/C_c}{(t_{hi} - t_{ci})} = \frac{240/8.05}{(80 - 20)} = 0.497$$

where t_{co} is the leaving air temperature.

c) The effectiveness-NTU relationships for a cross-flow heat exchanger with both fluids unmixed allow calculation of the effectiveness in terms of the capacity rate ratio Z and the NTU [the relationships are available from most heat transfer textbooks and, specifically, in Kays and London (1984)]. Given the effectiveness and capacity rate ratio, NTU = 0.804.

d) The heat transfer *UA* is then determined from the definition of the NTU.

$$UA = C_{min}\text{NTU} = (8.05)(0.804) = 6.472 \text{ kW/K}$$

Application to Cooling and Dehumidifying Coils

Analysis of air-cooling and dehumidifying coils requires coupled, nonlinear heat and mass transfer relationships. These relationships form the basis for all HVAC components with moisture transfer, including cooling coils, cooling towers, air washers, and evaporative coolers. Although the complex heat and mass transfer theory presented in many textbooks is often required for cooling coil design, simpler models based on effectiveness concepts are usually more appropriate for energy estimation. For example, the bypass factor is a form of effectiveness in the approach of the leaving air temperature to the apparatus dew-point, or coil surface, temperature.

The effectiveness-NTU method is typically developed and applied in analysis of sensible heat exchangers, but it can also be used to analyze other types of exchangers, such as cooling and dehumidifying coils, that couple heat and mass transfer. By redefining the state variables, capacity rates, and overall exchange coefficient of these enthalpy exchangers, the effectiveness concept may be used to calculate heat transfer rates and leaving fluid states. For sensible heat exchangers, the state variable is temperature, the capacity is the product of mass flow and fluid specific heat, and the overall transfer coefficient is the conventional overall heat transfer coefficient. For cooling and dehumidifying coils, the state variable becomes moist air enthalpy, the capacity has units of mass flow, and the overall heat transfer coefficient is modified to reflect enthalpy exchange. This approach is the basis for models by Brandemuehl (1993), Braun et al. (1989), and Threlkeld (1970). The same principles also underlie the coil model described in Chapter 23 of the 2012 *ASHRAE Handbook—HVAC Systems and Equipment*.

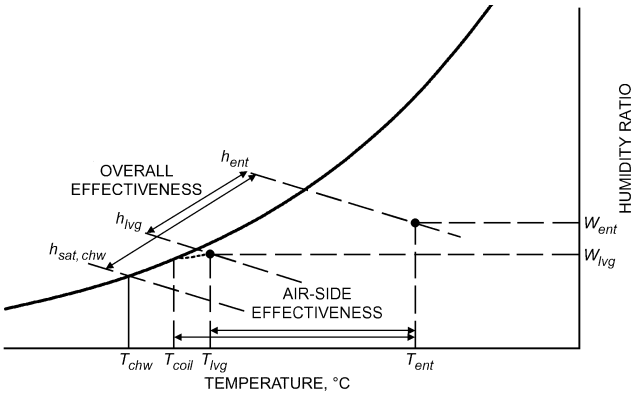

Fig. 8 Psychrometric Schematic of Cooling Coil Processes

The effectiveness model is based on the observation that, for a given set of entering air and liquid conditions, the heat and mass transfer are bounded by thermodynamic maximum values. Figure 8 shows the limits for leaving air states on a psychrometric chart. Specifically, the leaving chilled-water temperature cannot be warmer than the entering air temperature, and the leaving air temperature and humidity cannot be lower than the conditions of saturated moist air at the temperature of the entering chilled water.

Figure 8 also shows that performance of a cooling coil requires evaluating two different effectivenesses to identify the leaving air temperature and humidity. An overall effectiveness can be used to describe the approach of the leaving air enthalpy to the minimum possible value. An air-side effectiveness, related to the coil bypass factor, describes the approach of the leaving air temperature to the effective wet-coil surface temperature.

Effectiveness analysis is accomplished for wet coils by establishing a common state variable for both the moist air and liquid streams. As implied by the lower limit of the entering chilled-water temperature, this common state variable is the moist air enthalpy. In other words, all liquid and coil temperatures are transformed to the enthalpy of saturated moist air at the liquid or coil temperature. Changes in liquid temperature can similarly be expressed in terms of changes in saturated moist air enthalpy through a saturation specific heat $c_{p,sat}$ defined by the following:

$$c_{p,\,sat} = \frac{\Delta h_{l,\,sat}}{\Delta t_l} \tag{12}$$

Using the definition of Equation (12), the basic effectiveness relationships discussed in Chapter 4 can be written as

$$q = C_a(h_{a,\,ent} - h_{a,\,lvg}) = C_l(h_{l,\,sat,\,lvg} - h_{l,\,sat,\,ent}) \tag{13}$$

$$q = \varepsilon C_{min}(h_{a,\,ent} - h_{l,\,sat,\,ent}) \tag{14}$$

$$C_a = \dot{m}_a \tag{15}$$

$$C_l = \frac{(\dot{m}c_p)_l}{c_{p,\,sat}} \tag{16}$$

$$C_{min} = \min(C_a, C_l) \tag{17}$$

where

q = heat transfer from air to water, W
C = fluid capacity, kg/h

Licensed for single user. © 2021, ASHRAE, Inc.

m_a = dry air mass flow rate, kg/s
m_l = liquid mass flow rate, kg/s
$c_{p,l}$ = liquid specific heat, kJ/(kg·K)
$c_{p,sat}$ = saturation specific heat, defined by Equation (12), kJ/(kg·K)
h_a = enthalpy of moist air, kJ/kg
$h_{l,sat}$ = enthalpy of saturated moist air at the temperature of the liquid, kJ/kg

The cooling coil effectiveness of Equation (14) is defined, then, as the ratio of moist air enthalpies in Figure 8. As with sensible heat exchangers, effectiveness is also a function of the physical coil characteristics and can be obtained by modeling the coil as a counterflow heat exchanger. However, because heat transfer calculations are performed based on enthalpies, the overall transfer coefficient must be based on enthalpy potential rather than temperature potential. The enthalpy-based heat transfer coefficient UA_h is related to the conventional temperature-based coefficient by the specific heat:

$$q = UA\Delta t = UA_h\Delta h$$
$$UA_h = \frac{UA\Delta t}{\Delta h} = \frac{UA}{c_p} \quad (18)$$

A similar analysis can be performed to evaluate the air-side effectiveness, which identifies the leaving air temperature. Whereas the overall enthalpy-based effectiveness is based on an overall heat transfer coefficient between the chilled water and air, air-side effectiveness is based on a heat transfer coefficient between the coil surface and air.

As with sensible heat exchangers, the overall heat transfer coefficients *UA* can be determined either from direct calculation from coil properties or from manufacturers' performance data. A sensible heat exchanger is modeled with a single effectiveness and can be described by a single parameter *UA*, but a wet cooling and dehumidifying coil requires two parameters to describe the two effectivenesses shown in Figure 8. These parameters are the internal and external *UA*s: one describes heat transfer between the chilled water and the air-side surface through the pipe wall, and the other between the surface and the moist air. *UA* values can be determined from the sensible and latent capacity of a cooling coil at a single rating condition. A significant advantage of the effectiveness-NTU method is that the component can be described with as little as one measured data point or one manufacturer's design calculation.

4.4 PRIMARY SYSTEM COMPONENTS

Primary HVAC systems consume energy and deliver heating and cooling to a building, usually through secondary systems. Primary equipment generally includes chillers, boilers, cooling towers, cogeneration equipment, and plant-level thermal-storage equipment. In particular, primary equipment generally represents the major energy-consuming equipment of a building, so accurate characterization of building energy use relies on accurate modeling of primary equipment energy consumption.

Boilers

The literature on boiler models is extensive, ranging from steady-state performance models (DeCicco 1990; Lebrun 1993) to detailed dynamic simulation models (Bonne and Jansen 1977; Lebrun et al. 1985), to a combination of these two schemes (Laret 1991; Malmström et al. 1985). However, the input information required for these models is not often readily available, and these models should be considered only in more complex situations (e.g., large boilers in large buildings, district heating systems, cogeneration systems), where a complete, detailed representation of heat distribution, emission, and operation and control under varying external conditions is warranted.

In most current energy-estimating programs, the performance of boilers is represented by regression equations and a full-load efficiency value as described in the section on Empirical (Regression-Based) Models. Those equations typically represent the boiler efficiency under varying load conditions and, in some cases, the equations also account for water temperature conditions. When using these regression-based models, two important issues to understand are efficiency rating conditions and the off-design efficiency calculation method used by the energy-estimating program.

Rating Conditions. The primary rating condition relevant for fuel-fired boiler efficiency is the entering water temperature, which is the return water temperature in most building heating applications. Efficiency improves as the return water temperature drops, because more heat can be extracted from exhaust gases. A condensing boiler can reach efficiencies up to 98% with entering water at 27°C. The minimum return water temperature for noncondensing boilers is typically about 60°C, because lower temperatures lead to condensation and damaging corrosion, and efficiency under that condition is usually in the range of 80% to 85%. The important point to consider when entering a value for fuel-fired boiler efficiency in an energy-estimating program is the assumption made by the program about rating conditions. For example, the DOE2.2 program expects noncondensing boiler efficiency values to correspond to 71°C entering water temperature and condensing water boiler efficiency values to correspond to 27°C entering water temperature. More information on boiler design and rating conditions is provided in Chapter 32 of the 2020 *ASHRAE Handbook—HVAC Systems and Equipment*.

Off-Design Conditions. Another important consideration in the use of energy-estimating programs is the type of model used to represent off-design conditions (i.e., how the efficiency is assumed to change at partial load or as the water temperature conditions change). Some models account only for changes in efficiency with changes in load. Other models consider both load and entering water temperature, and still others consider load and leaving water temperature. Some programs offer a choice of models. For best accuracy, models that account for load and entering water temperature are preferred.

Figures 9 and 10 show examples of how boiler efficiency is represented by different types of models. Figure 9 shows a model in which boiler efficiency is a function of part-load ratio alone. Different regression equation coefficients are used for atmospheric-draft and forced-draft boilers, and the forced-draft units are represented with better part-load efficiency. An implicit assumption of this model is that entering water temperature is in a range where it does not have a significant impact on efficiency, which may be reasonable for noncondensing boilers. Figure 10 shows a model for a condensing boiler in which efficiency is a function of both part-load ratio and entering water temperature. This model shows that efficiency increases as entering water temperature decreases and as load decreases.

Chillers

Models representing energy consumption of chillers include both first-principles models and empirical models. Examples of first-principles models include detailed modeling techniques described in the ASHRAE *HVAC 1 Toolkit* (Lebrun et al. 1999) and the Gordon-Ng model (Gordon 2000). A discussion of the Gordon-Ng model is provided in the Data-Driven Modeling section, presented as an example of a physical model. From a practical point of view, the data required as inputs to these first-principles models will not always be available. Most current energy-estimating programs use empirical models to represent chiller performance. Hydeman et al. (2002) compares the prediction capabilities of several types of models.

Empirical chiller models typically comprise a set of regression equations that represent variations in cooling capacity and efficiency in operation. A common implementation consists of three polynomial equations. One represents variation in cooling capacity

Licensed for single user. © 2021, ASHRAE, Inc.

as a function of temperature conditions. A second represents the change in efficiency with changing temperature conditions. The third equation represents efficiency as a function of part-load ratio. The following are common inputs to empirical chiller models:

- Full-load efficiency
- Part-load ratio
- Chilled-water supply temperature (temperature leaving the evaporator)
- For water-cooled chillers: condenser water return temperature (temperature entering the condenser)
- For air-cooled chillers: outdoor air dry-bulb temperature

Different types of chillers have different performance characteristics, and their performance is typically represented by different sets of regression equation coefficients. Important chiller design differences include type of condenser (air- or water-cooled), type of compressor (reciprocating, screw, or centrifugal), and unloading mechanism (e.g., inlet vanes or variable-speed compressor control). Chapter 43 of the 2020 *ASHRAE Handbook—Systems and Equipment* provides descriptions of different types of chillers.

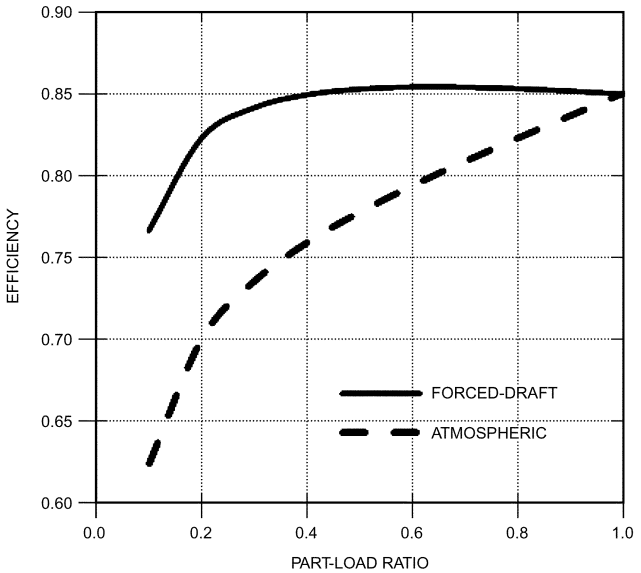

Fig. 9 Example Boiler Model: Efficiency as Function of Part-Load Ratio

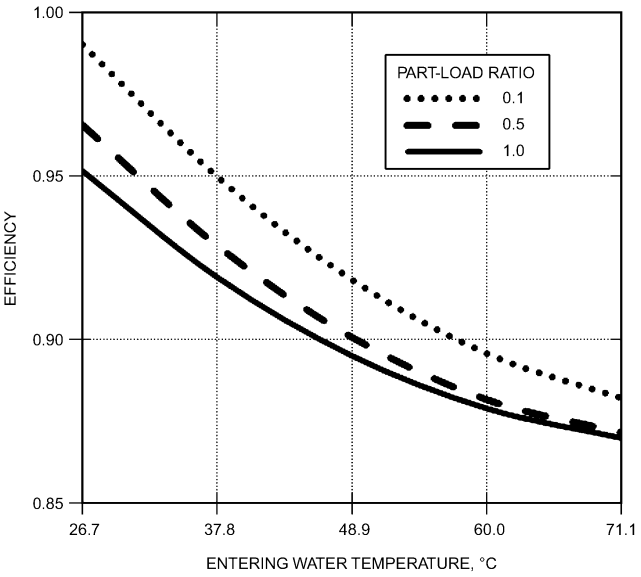

Fig. 10 Example Boiler Model: Efficiency as Function of Part-Load Ratio and Entering Water Temperature

Coefficients for chiller models are often supplied as defaults by energy-estimating programs. However, when the intent of analysis is to compare the energy performance of specific chiller alternatives, the recommended practice is to obtain performance data for the specific chillers to create calibrated sets of coefficients for each chiller. Manufacturers can typically provide such data, and it is very important to obtain a set of data representing the full range of potential operating conditions. The process of calculating coefficients for a chiller model is described in Hydeman and Gillespie (2002). For another discussion of empirical chiller models and the process of determining model coefficients, see the *HVAC Simulation Guidebook*, vol. 1 (Energy Design Resources 2012).

Cooling Tower Model

A cooling tower is used in primary systems to reject heat from the chiller condenser. Controls typically manage tower fans and pumps to maintain a desired water temperature entering the condenser. Like cooling and dehumidifying coils in secondary systems, cooling tower performance has a strong influence on the chiller's energy consumption. In addition, tower fans consume electrical energy directly.

Fundamentally, a cooling tower is a direct contact heat and mass exchanger. Equations describing the basic processes are given in Chapter 6 and in many HVAC textbooks. Chapter 40 of the 2020 *ASHRAE Handbook—HVAC Systems and Equipment* describes the specific performance of cooling towers. Performance subroutines are also available in Lebrun et al. (1999) and TRNSYS (2012).

For energy calculations, cooling tower performance is typically described in terms of the outdoor wet-bulb temperature, temperature drop of water flowing through the tower (range), and difference between leaving water and air wet-bulb temperatures (approach). Simple models assume constant range and approach, but more sophisticated models use rating performance data to relate leaving water temperature to the outdoor wet-bulb temperature, water flow, and airflow. Simple cooling tower models, such as those based on a single overall transfer coefficient that can be directly inferred from a single tower rating point, are often appropriate for energy calculations.

Variable-Speed Vapor-Compression Heat Pump Model

Although packaged equipment is most often modeled by empirical functions fit to manufacturers' data, methods are also needed to model and evaluate advanced equipment such as variable-speed heat pumps. Zakula et al. (2011) detail a component-based heat pump model, including variable-speed fan and pump models; variable refrigerant-, air-, and water-side heat transfer coefficients; variable pressure drops; and staged compressors, one or more of which may operate over a wide speed range. Such models can produce performance maps for new equipment designs, including designs in which refrigerant and transport fluid flow rates and condenser subcooling are coordinated as optimized functions of conditions and imposed load (Zakula et al. 2012). A tricubic fit to such performance maps has been shown to represent performance accurately over a wide range of conditions and load.

As a special heat pump model, variable-refrigerant-flow (VRF) systems vary the refrigerant flow to meet the dynamic zone thermal loads. Hong et al. (2016) developed a new VRF heat pump model, which has physics-based component models. This VRF model, implemented in EnergyPlus, (1) enables advanced controls, including variable evaporating and condensing temperatures in the indoor and

Licensed for single user. © 2021, ASHRAE, Inc.

outdoor units, and variable fan speeds based on the temperature and zone load in the indoor units; (2) adds a detailed refrigerant pipe heat loss calculation using refrigerant flow rate, operational conditions, pipe length, and pipe insulation materials; (3) increases accuracy of simulation especially in partial load conditions; and (4) improves the usability of the model by significantly reducing the number of user input performance curves. A new heat recovery VRF model was also developed and is implemented in EnergyPlus, which enables more accurate modeling of heat recovery between zones with simultaneous cooling and heating loads. The new VRF models in EnergyPlus were validated with measured performance data from real buildings or laboratory experiments.

Ground-Coupled Systems

Ground-coupled systems use the ground as the source/sink for heating or cooling a building. These types of systems are described in detail in Chapter 34 of the 2019 *ASHRAE Handbook—HVAC Applications*. For the most part, the HVAC system components used in these systems are similar to those used in other HVAC systems and do not require any special techniques to estimate their performance. The exception to this is simulating energy exchange with the ground.

Energy is exchanged with the ground through direct use of water from the ground or through ground heat exchangers. With a direct-use system, the temperature entering the HVAC system from the ground is often considered to be constant or to vary only seasonally. This assumption can be valid when the extraction and injection wells are far enough apart to prevent mixing of the aquifer. A number of aquifer storage performance models have been developed for use with HVAC systems, but these have not yet reached mainstream simulation programs.

For simulating performance of ground heat exchangers, two different techniques have been developed: the duct ground storage (DST) model introduced by Hellstrom (1989) that calculates the transient thermal process of borehole fields, and a thermal response factor (*g*-function) approach based on work of Eskilson (1987). Both techniques give a relation between the heat extracted (or rejected) from the ground per unit borehole length and the borehole wall temperature. Both of these methods have been integrated into whole-building simulation programs.

4.5 MODELING OF SYSTEM CONTROLS

Building control systems are hierarchical: higher-level, supervisory controls typically generate set points for lower-level, local loop controls. Supervisory controls include reset and optimal control (see Chapter 42 of the 2019 *ASHRAE Handbook—HVAC Applications*) and often have a large effect on energy consumption. Local loop controllers may also affect energy performance; for example, proportional-only room temperature control results in a trade-off between energy use and comfort. Faults in control systems and devices can also affect energy consumption (e.g., leaking valves and dampers can significantly increase energy use). It is particularly important to account for these departures from ideal behavior when simulating performance of real buildings using calibrated models. Modeling and simulation of some supervisory control functions are increasingly handled by whole-building simulation programs, but very advanced optimal controls such as receding horizon control are not. Simulation of local loop controls also requires more specialized, component- or equation-based modeling environments.

Modern control systems, particularly direct digital controls (DDC), typically use integral action to drive the controlled variable to its set point. For energy modeling purposes, the controlled variable (e.g., supply air temperature) can be treated as being at the set point unless system capacity is insufficient. The simulation must determine whether the capacity required to meet set point exceeds available capacity. If it does, the available capacity is used to determine the actual value of the controlled variable. Where there is only proportional action, the resulting relationship between the controlled variable and the output of the system can be used to determine both values. For example, the action of a conventional pneumatic room temperature controller can be represented by a function relating heating and cooling delivery to space temperature. Similarly, supply air temperature reset control can be modeled as a relationship between outdoor or zone temperature and coil or fan discharge temperature. An accurate secondary system model must ensure that all controls are properly represented and that the governing equations are satisfied at each simulation time step. This often creates a need for iteration or for use of values from an earlier solution point.

Controls on space temperature affect the interaction between loads calculations and the secondary system simulation. A realistic model might require a dead band in space temperature in which no heating or cooling is called for; within this range, the secondary system operates at zero capacity, and the true space temperature must be modeled accordingly. If the thermostat has proportional control between zero and full capacity, the space temperature rises in proportion to the load during cooling and falls similarly during heating. Capacity to heat or cool also varies with space temperature after the control device has reached its maximum because capacity is proportional to the difference between supply and space temperatures. Failure to properly model these phenomena may result in overestimating energy use.

4.6 INTEGRATION OF SYSTEM MODELS

Energy calculations for secondary systems involve construction of the complete system from the set of HVAC components. As an example, consider a process for simulating a variable-air-volume (VAV) system, a single-path system that controls zone temperature by modulating airflow while maintaining constant supply air temperature. VAV terminal units, located at each zone, adjust the quantity of air reaching each zone depending on its load requirements. Reheat coils may be included to provide required heating for perimeter zones or to prevent overcooling of lightly loaded zones.

This VAV system simulation consists of a central air-handling unit and a VAV terminal unit with reheat coil located at each zone, as shown in Figure 11.The central air-handling unit includes a fan, cooling coil, preheat coil, and outdoor air economizer. Supply air leaving the air-handling unit is controlled to a fixed set point. The VAV terminal unit at each zone varies airflow to meet the cooling load. As zone cooling load decreases, the VAV terminal unit decreases zone airflow until the unit reaches its minimum position. If the cooling load continues to decrease, the reheat coil is activated to meet the zone load. As supply air volume leaving the unit decreases, fan power consumption also reduces. A variable-speed drive is used to control the supply fan.

The simulation is based on system characteristics and zone design requirements. For each zone, the inputs include sensible and latent loads, zone set-point temperature, and minimum zone supply-air mass flow. System characteristics include supply air temperature set point; entering water temperature of reheat, preheat, and cooling coils; minimum mass flow of outdoor air; and economizer temperature/enthalpy set point for minimum airflow.

The algorithm for performing calculations for this VAV system is shown in Figure 12. The algorithm directs sequential calculations of system performance. Calculations proceed from the zones along the return air path to the cooling coil inlet and back through the supply air path to the cooling coil discharge. An alternative finite-state machine (FSM) approach is found in Chapter 42 of the 2019 *ASHRAE Handbook—HVAC Applications*.

Moving back along the supply air path, the fan entering air temperature is calculated by setting fan outlet air temperature to the

Fig. 12 Algorithm for Calculating Performance of VAV with System Reheat

system design supply air temperature. The known fan inlet air temperature is then used as both the cooling coil and preheat coil discharge air temperature set point. Moving along the return air path, the cooling coil entering air temperature can be determined by sequentially moving through the economizer cycle and preheat coil.

Unlike temperature, the humidity ratio at any point in a system cannot be explicitly determined because of the dependence of cooling coil performance on the mixed air humidity ratio. The latent load defines the difference between zone humidity and supply air humidity. However, the humidity ratio of supply air depends on the humidity ratio entering the coil, which in turn depends on that of the return air. This calculation must be performed either by solving simultaneous equations or, as in this case, iteration.

Assuming a trial value for the humidity ratio at the cooling coil discharge (e.g., 13°C, 90% rh), the humidity ratio at all other points throughout the system can be calculated. With known cooling coil inlet air conditions and a design discharge air temperature, the inverted cooling coil subroutine iterates on the coil fluid mass flow to converge on the discharge air temperature with the discharge air humidity ratio as an output. The cooling coil discharge air humidity ratio is then compared to the previous discharge humidity ratio. Iteration continues through the loop several times until the values of the cooling coil discharge air humidity ratio stabilize within a specified tolerance.

This basic algorithm for simulation of a VAV system might be used in conjunction with a heat balance type of load calculation. For a weighting factor approach, it would have to be modified to allow zone temperatures to vary and consequently zone loads to be readjusted. It should also be enhanced to allow possible limits on reheat temperature and/or cooling coil limits, zone humidity limits, outdoor air control (economizers), and/or heat-recovery devices, zone exhaust, return air fan, heat gain in the return air path because of lights, the presence of baseboard heaters, and more realistic control profiles. Most current building energy programs incorporate these and other features as user options, as well as algorithms for other types of systems.

5. LOW-ENERGY SYSTEM MODELING

5.1 NATURAL AND HYBRID VENTILATION

Natural ventilation refers to the introduction of outdoor air into a building via intentionally provided openings (e.g., windows and trickle ventilators) whereby airflow is driven by naturally occurring forces such as wind and buoyancy (stack effect) to provide fresh air and ventilation cooling (free cooling). The movement of air resulting from natural ventilation can also provide direct cooling [see Aynsley et al. (1977) and Olgyay (1973)]. Hybrid or mixed-mode ventilation refers to the use of mechanical means to supplement or enhance natural ventilation when the driving forces of wind and/or buoyancy are unable to meet the required ventilation rate or thermal comfort targets. Hybrid ventilation can be loosely divided into three categories:

Licensed for single user. © 2021, ASHRAE, Inc.

fully parallel natural and mechanical ventilation, fan-assisted natural ventilation, and stack- and wind-assisted mechanical ventilation (Hybrid Ventilation Centre 2002). Regardless of which system is implemented, control of the system components and interaction between ventilation modes is critical to system effectiveness.

The design of natural ventilation systems requires careful consideration of the climate in which the building is located. Not only must prevailing outdoor temperatures, wind speed, and direction be accounted for to gage the forces available to drive natural ventilation, but outdoor temperature and humidity can affect the level of thermal comfort attainable within the building. However, even in climates where external air temperatures are relatively high, it may be possible to use natural ventilation to deliver acceptable thermal comfort. This can be done in combination with other passive design measures such as exposed thermal mass, solar shading, and nighttime ventilation cooling, or as part of a hybrid ventilation solution (Lomas et al. 2007). Also, environmental pollutants can affect the level of indoor air quality (IAQ) that is achievable without the benefit of filtering the outdoor air as it enters the building. Simulation of natural and hybrid ventilation systems should capture as many of these aspects as possible. At the very least, consideration should be given to modeling and predicting the likely performance of the ventilation strategy in terms of ventilation rates and indoor environmental quality, including thermal comfort of the building occupants. Chapters 13 and 16, respectively, discuss modeling and ventilation (including natural ventilation) in more detail, and CIBSE (2005) provides a guide to designing natural ventilation systems in nondomestic buildings.

Natural Ventilation

Tools for modeling natural ventilation systems fall into three main categories, discussed in the following sections. Although these modeling tools can be applied individually, simulation and design are better served by using the capabilities of multiple types of tools to provide a more comprehensive analysis.

Simplified Models. Simplified models can be used at the initial design stages for solving algebraic (nondifferential) equations to determine climate suitability, ventilation flow rates, and zone-average temperatures. This can be valuable information, especially at the concept design stage, when architects require approximate information about the feasibility of implementing natural ventilation and determining size and position of ventilation openings. The equations typically used in these models can be found in Chapter 16 and in CIBSE (2005). However, there are many other examples of simplified techniques used to predict the behavior of specific aspects of natural ventilation. For example, Linden et al. (1990) developed analytical models for predicting interface heights in stratified regimes, and Chenvidyakarn and Woods (2005) used analytical methods to predict solution multiplicity in large-volume spaces.

Climate-suitability analysis methods and tools are available for the predesign phase. These relatively simple models provide a first-order estimate of the potential effectiveness of natural ventilation to provide direct ventilation cooling, nighttime cooling, and thermal comfort, based on climate data representative of the building location. Axley and Emmerich (2002) present a climate suitability design method based on a single-zone, steady-state energy balance, and thermal comfort criteria. Lomas et al. (2007) present an analysis of ambient temperature and moisture content with respect to thermal comfort criteria plotted on a psychrometric chart.

One common form of analytical model involves first solving equations to determine the driving pressures caused by wind and buoyancy forces. These driving pressures are calculated with reference to the neutral pressure level (CIBSE 2005) and are used at proposed opening locations as input to mathematical representations of the airflow through the openings (e.g., the orifice flow equation). Given the design airflow rate, these equations can then be used to calculate effective opening areas. Axley (2001) presents an opening sizing method that was subsequently formulated as a software tool (Emmerich et al. 2011; Dols et al. 2012). These methods and tools can also account for multiple openings and user-specified airflow patterns through a building (e.g., into the building via a trickle ventilator, through an air transfer grill, then out through a stack). As outlined in CIBSE (2005), driving pressures should be calculated for representative design scenarios when wind speeds and internal/external temperature differences are relatively low, because these will determine the maximum opening sizes required. Illustrations of how some of these simplified models can be used are given in Axley (2001), CIBSE (2005), and Emmerich et al. (2012).

Network Airflow Models. Network airflow models, also referred to as multizone models, are discussed in Chapter 13. They are more complex than the simplified models, because they solve the simultaneous (interdependent) airflows and pressure differences between multiple, interconnected building zones and the outdoors and are typically applied to the building in its entirety. In particular, using airflow network characteristics (e.g., airflow resistances) and climate data (along with assumed temperatures within the building), network airflow models calculate combined buoyancy- and wind-driven pressures and the rate and direction of airflows for all openings in the model. Some models can also be used to perform interzone contaminant mass transport calculations that can be useful in analyzing IAQ (Axley 2007) and simulating contaminant-based ventilation rate control schemes (e.g., CO_2-based demand controlled ventilation) (Dols et al. 2016a). Network airflow models can be coupled with dynamic thermal simulation programs to calculate the internal zone temperatures used in the network airflow model (Clarke 2001; Dols et al. 2016a, 2016b; U.S. Department of Energy 1996-2016).

A distinct challenge in the use of network airflow models is selecting mathematical representations and parameters that best capture the airflow characteristics of the ventilation components. For example, airflow resistances can be described using a discharge coefficient (or pressure loss factor) and the effective opening area. However, specifying the component characteristics requires a clear understanding of how the model interprets these values. Details of the terminology used can be found in Jones et al. (2016).

Computational Fluid Dynamics. Computational fluid dynamics (CFD) is also discussed in Chapter 13. CFD models represent the most complex class of airflow models and can be valuable for simulating natural ventilation, including the effects of wind on the building envelope pressures and internal airflow patterns that develop as a result of various boundary conditions and representative portions of the building interior. CFD is not typically applicable to simulating entire buildings over long-term, transient time frames. However, there are many strategies available for using CFD in the design and analysis of natural ventilation systems; for example, Malkawi et al. (2016) describes using both CFD and a combined network airflow and energy calculation method.

The main feature that sets CFD models apart from numerical and network airflow models is the use of a fine mesh comprising many thousands of cells throughout the computational domain. For each cell, nonlinear partial differential equations are solved to predict the air speed, air temperature, turbulence, and pressure in each cell. This provides a very detailed representation of the spatial distribution of the airflow and has the advantage of highlighting drafts, warm zones, and thermal stratification. Boundary conditions are required in CFD models to drive the flow. They include temperature or heat flux values at solid surfaces and conditions of air speed and turbulence at openings. Surface temperatures are often obtained from the results of a dynamic thermal network simulation model. This approach has the advantage of including the effects of radiation without solving a separate radiation model in

Licensed for single user. © 2021, ASHRAE, Inc.

the CFD simulation. Boundary conditions at natural ventilation openings must be specified with care, because neither the flow rate nor the internal temperature are known a priori. This can be overcome by using the orifice flow equation, which simply provides a relationship between the flow rate and pressure difference across openings [e.g., Durrani et al. (2015)]. Another important challenge to be aware of when using CFD is the need for an iterative approach to solve the governing, nonlinear equations. It is therefore important to appreciate that simulation run times can be long (i.e., several hours), and that techniques for controlling convergence are often needed, especially in buoyancy-driven natural ventilation flows where driving pressures are small. Often, this control can be achieved by using a transient simulation or false time-stepping [e.g., Kaye et al. (2009)].

Hybrid Ventilation

When design tools have predicted that natural ventilation is unlikely to be sufficient for providing adequate IAQ and thermal comfort and a hybrid strategy has been proposed, it is useful to carry out some modeling of the system to provide confidence and identify likely energy implications. This can be done by enhancing the techniques described previously for modeling natural ventilation with network airflow and CFD models.

Ventilation and energy performance of buildings with natural or mixed-mode ventilation systems can be simulated using whole-building network airflow models, including those that may be combined with or directly incorporate a whole-building thermal analysis model (e.g., EnergyPlus) (Dols et al. 2015, 2016b). The energy module sends information about the building, ambient weather conditions, and zone temperatures to the network airflow module. This information is used to calculate infiltration, ventilation, and interzone airflow by the airflow network module; the results will be sent back to the energy module and used in the next time step's heat balance. In addition to the airflow characteristics through openings such as windows and transfers grilles connecting spaces, models of hybrid systems must also include fan airflow models (e.g., design flow rates and fan performance curves).

One of the primary challenges in modeling hybrid ventilation systems is simulating the controls systems that are inherently associated with these systems. Hybrid ventilation schemes may require multiple modes of operation depending on variations in climate, including seasonal, daily, and short-term local variations. These modes of operation can vary in complexity because of the number and type of system components involved. In buildings with automatically controlled ventilation openings or fans, the control system may require parameters such as wind speed and direction, among others, to open, close, or adjust openings; turn fans on/off; or adjust flow rates. This range of flexibility varies among available models. However, it is likely that users will need to input sensors, actuators, and control logic per the input methods of the tool being used, and the model should predict system performance accordingly (e.g., variations in fan airflow, ventilation opening status). Some modeling tools or combinations of tools enable transient simulations to be performed with user-defined control algorithms (e.g., DOE 2015; Dols et al. 2016a; Wetter 2011), and these may be used for performing annual simulations or at least over periods of time that address the various modes of operation.

5.2 DAYLIGHTING

Daylighting in buildings is used to reduce the use of electric lighting systems. A proper daylighting design provides improved illumination for occupants and reduces a building's energy use. A building's orientation, window size and properties, and shading (e.g., overhangs and fins) affect daylight illuminance at specific points in a space. Whole-building energy simulation programs, such as EnergyPlus and DOE-2.2/eQUEST, can keep track of how much supplemental electric lighting is reduced when daylighting is used. In addition, energy simulation programs calculate the thermal heat loss and gain associated with the fenestration for daylighting. Electric lighting level is determined by fraction of lighting area, lighting type, daylight illuminance level, and targeted illuminance. Additional details regarding daylighting and electric lighting control strategies are described in Chapter 15.

Historically, daylighting analysis programs have used three components to calculate the amount of daylight coming through a window or skylight: **sky component (SC)**, **external reflected component (ERC)**, and **internal reflected component (IRC)**.

Commonly used methods for estimating the IRC include the split-flux, radiosity, and ray-tracing methods. In the 1950s, the **split-flux method** was used to estimate the IRC using empirical formulas (Hopkinson et al. 1954). In this method, Hopkinson et al. assumed the interior surfaces of a room were a connected spherical shape and were perfectly diffused with no inner obstacles, which worked best in a room shaped as a cube without internal partitions (Winkelmann and Selkowitz 1985). Tregenza (1989) presented a modification to the split-flux method to account for large external obstacles such as overhangs. Figure 13 shows the concept of the split-flux method [f_s = window factor for the light incident on the window from sky, R_{fw} = average reflectance of the floor and those parts of the walls below the plane of the mid-height of the window (excluding the window-wall), f_g = window factor for the light incident on the window from ground, and R_{cw} = average reflectance of the ceiling and those parts of the walls above the plane of the mid-height of the window (excluding the window-wall)] (Oh and Haberl 2016c). The split-flux method is widely used in whole-building energy simulation programs such as DOE-2.1E (Winkelmann et al. 1993), DOE-2.2/eQUEST (LBNL 1998), and EnergyPlus (U.S Department of Energy 1996-2016).

The **radiosity method** more accurately analyzes various geometries and reflectances than the split-flux method but less accurately than the ray-tracing method. The radiosity method provides an accurate method to analyze a zone where object-to-object reflection exists between diffuse surfaces in a zone. This procedure uses the energy balance concept for analyzing radiative heat transfer (i.e., radiant-flux transfer), which has been widely used by thermal engineers (Goral et al. 1984; O'Brien 1955). The radiant-flux transfer analysis between surfaces applies the light-flux transfer analysis in an enclosure using a lumped parameter network (O'Brien 1955; Oppenheim 1954). The radiosity method uses the electrical network approach to account for the initial and interreflected luminous emittances (i.e., the light-flux transfer). The surface reflectances (i.e.,

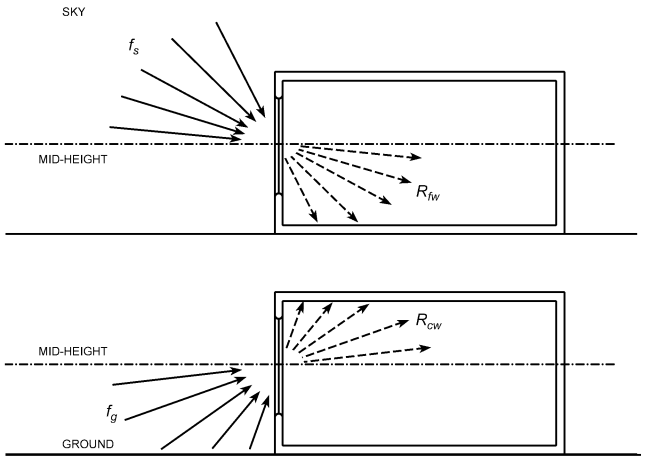

Fig. 13 Split-Flux Method

(Oh and Haberl 2016c)

the radiant properties) and the view factors (i.e., the relative geometry properties) of the luminous emittances are defined as the resistances in the network (O'Brien 1955). The method is used in Lumen Micro and in one of the daylighting models of EnergyPlus v.1.x and higher.

Finally, **ray tracing** is the most advanced and accurate method for analyzing the interreflections between both diffuse and specular surfaces in complex enclosures (Baker et al. 1993; Ward and Rubinstein 1988; Ward et al. 1988). The method follows the light rays in an enclosure and takes into account all the characteristics of various surface geometries and surface reflectances. The method was originally developed to create high-quality computer graphics in complex scenes (Baker et al. 1993). Ray tracing is typically used to analyze daylight illuminance itself, instead of being combined with whole-building energy simulation programs to account for electric lighting. The ray-tracing method is used in Radiance (Ward 1994) and DIVA (Jakubiec and Reinhart 2011). Additional details can be found in Oh and Haberl (2016c). The forward ray-tracing method traces the rays of light generated from a source of light to the eye of the viewer (Kuchkuda 1988). Figure 14 shows the concept of the forward ray-tracing method (Grantham 2008; Oh and Haberl 2016c). The backward ray-tracing method traces a ray of each point (i.e., each pixel) backwards from the viewer through the image plane to the object (Arvo 1986; Kuchkuda 1988; Ward and Rubinstein 1988; Ward et al. 1988). Figure 15 shows this concept (Grantham 2008; Oh and Haberl 2016c).

5.3 PASSIVE HEATING

Passive buildings use solar heating directly (i.e., without pumps, blowers, etc.) and sometimes include natural passive cooling. Solar direct gain, sunspaces, Trombe walls, and passive downdraft cool towers are examples of passive solar strategies. Detailed simulation programs such as TRNSYS (Duffie and Beckman 2013) and SUNREL (Deru et al. 2002) can be used to analyze passive solar energy applications and building loads. TRNSYS and SUNREL use a thermal network approach (Paschkis 1942) to analyze the time-varying solar radiation and heat transfer in a building. In addition, simplified methods such as the solar load ratio (SLR) method (Balcomb and Hedstrom 1976) and the unutilizability method (Monsen and Klein 1980; Monsen et al. 1981) can be used to analyze passive solar systems. Computer simulations can be used to calculate the time-dependent, short-term, and long-term performance of solar energy systems in detail. Simplified methods that require fewer calculations than hourly solar simulations (Klein 1993) can be used to estimate the long-term performance of solar energy systems. Passive solar design analysis is useful for engineers to select and size solar systems when input data and on-site solar irradiation data may not be available (Evans et al. 1982). Additional details can be found in Oh and Haberl (2016b).

6. DATA-DRIVEN MODELING

The objective of data-driven (inverse) modeling is to determine a mathematical description of the system and to estimate system parameters when the input and output variables are known and measured. The data-driven approach is relevant only when the system has already been built and actual performance data are available for model development, calibration, and/or identification.

There are several important uses of data-driven models. They can be used to verify savings for implemented energy conservation measures, where the data-driven model provides an estimate of baseline energy consumption for comparison to post-retrofit energy consumption. Data-driven models can be used with energy management and control systems to predict energy use (Kreider and Haberl 1994). Hourly or daily comparisons of measured versus predicted energy use can be used to determine whether systems are being left on unnecessarily or are in need of maintenance. Combinations of predicted energy use and a knowledge-based system can indicate above-normal energy use and diagnose the possible cause of the malfunction if sufficient historical information has been previously gathered (Haberl and Claridge 1987). Hourly systems that use artificial neural networks have also been constructed (Kreider and Wang 1991).

6.1 CATEGORIES OF DATA-DRIVEN METHODS

Data-driven methods for energy-use estimation in buildings and related HVAC&R equipment can be classified into two broad categories. These approaches differ widely in data requirements, time and effort needed to develop the associated models, user skill requirements, and sophistication and reliability provided.

Empirical or "Black-Box" Approach

With an empirical approach, a simple or multivariate regression model is identified between measured energy use and the various influential parameters (e.g., climatic variables, building occupancy). The form of the regression models can be either purely statistical or loosely based on some basic engineering formulation of energy use in the building. In any case, the identified model coefficients are such that no (or very little) physical meaning can be assigned to them. This approach can be used with any time scale (monthly, daily, hourly or subhourly) if appropriate data are available. Single-variate, multivariate, change point, Fourier series, and artificial neural network (ANN) models fall under this category. Least-squares regression is the most common approach to model identification, although more sophisticated regression techniques

Licensed for single user. © 2021, ASHRAE, Inc.

such as maximum likelihood and two-stage regression schemes can also be used.

Statistical regression models are usually adequate for estimating savings in demand-side management (DSM) programs for conventional energy conservation measures (lighting retrofits, air handler retrofits such as CV to VAV retrofits) and for baseline model development in energy conservation measurement and verification (M&V) projects (Claridge 1998; Dhar 1995; Dhar et al. 1998, 1999a, 1999b; Fels 1986; Haberl and Culp 2012; Haberl et al. 1998; Katipamula et al. 1998; Kissock et al. 1998; Krarti et al. 1998; Kreider and Wang 1991; MacDonald and Wasserman 1989; Miller and Seem 1991; Reddy et al. 1997; Ruch and Claridge 1991).

Statistical models may also be appropriate for modeling equipment such as pumps and fans, and even more elaborate equipment such as chillers and boilers, if the necessary performance data are available (Braun 1992; Chen et al. 2005; Englander and Norford 1992; Lorenzetti and Norford 1993; Phelan et al. 1996). Although this approach allows detection or flagging of equipment or system faults, it is usually of limited value for diagnosis and online control.

Gray-Box Approach

The gray-box approach first formulates a physical model to represent the structure or physical configuration of the building or HVAC&R equipment or system, and then identifies important parameters representative of certain key and aggregated physical parameters and characteristics by statistical analysis (Rabl and Riahle 1992). This approach requires a high level of user expertise both in setting up the appropriate modeling equations and in estimating these parameters. Often an intrusive experimental protocol is necessary for proper parameter estimation. This approach has great potential, especially for fault detection and diagnosis (FDD) and online control, but its applicability to whole-building energy use is limited. Examples of parameter estimation studies applied to building energy use are Andersen and Brandemuehl (1992), Braun (1990), Gordon and Ng (1995), Guyon and Palomo (1999a), Hammarsten (1984), Rabl (1988), Reddy (1989), Reddy et al. (1999), Sonderegger (1977), and Subbarao (1988).

6.2 TYPES OF DATA-DRIVEN MODELS

Steady-state models do not consider effects such as thermal mass or capacitance that cause short-term temperature transients. Generally, these models are appropriate for monthly, weekly, or daily data and are often used for baseline model development. **Dynamic models** capture effects such as building warm-up or cooldown periods and peak loads, and are appropriate for building load control, FDD, and equipment control. A simple criterion to determine whether a model is steady-state or dynamic is to look for the presence of time-lagged variables, either in the response or regressor variables. Steady-state models do not contain time-lagged variables.

Steady-State Models

Several types of steady-state models are used for both building and equipment energy use: single-variate, multivariate, polynomial, and physical.

Single-Variate Models. Single-variate models (i.e., models with one regressor variable only) are perhaps the most widely used. They formulate energy use in a building as a function of one driving force that affects building energy use. An important aspect in identifying statistical models of baseline energy use is the choice of the functional form and the independent (or regressor) variables. Extensive studies (Fels 1986; Katipamula et al. 1994; Kissock et al. 1993; Reddy et al. 1997) have indicated that the outdoor dry-bulb temperature is the most important regressor variable for typical buildings, especially at monthly time scales but also at daily time scales.

The simplest steady-state data-driven model is one developed by regressing monthly utility consumption data against average billing-period temperatures. The model must identify the balance-point temperatures (or change points) at which energy use switches from weather-dependent to weather-independent behavior. In its simplest form, the 18.3°C degree-day model is a change-point model that has a fixed change point at 18.3°C. Other examples include three- and five-parameter Princeton scorekeeping methods (PRISM) based on the variable-base degree-day concept (Fels 1986). An allied modeling approach for commercial buildings is the four-parameter (4-P) model developed by Ruch and Claridge (1991), which is based on the monthly mean temperature (and not degree-days). Table 4 shows some commonly used model functional forms. The three parameters are a weather-independent base-level use, a change point, and a temperature-dependent energy use, characterized as a slope of a line that is determined by regression. The four parameters include a change point, a slope above the change point, a slope below the change point, and the energy use associated with the change point. A data-driven bin method has also been proposed to handle more than four change points (Thamilseran and Haberl 1995).

Figure 16 shows several types of steady-state, single-variate data-driven models. Figure 16A shows a simple one-parameter, or constant, model, and Table 4 gives the equivalent notation for calculating the constant energy use using this model. Figure 16B shows a steady-state two-parameter (2-P) model where b_0 is the y-axis intercept and b_1 is the slope of the regression line for positive values of x, where x represents the ambient air temperature. The 2-P model represents cases when either heating or cooling is always required.

Figure 16C shows a three-parameter change-point model, typical of natural gas energy use in a single-family residence that uses gas for space heating and domestic water heating. In the notation of Table 4 for the three-parameter model, b_0 represents the baseline energy use and b_1 is the slope of the regression line for values of ambient temperature less than the change point b_2. In this type of notation, the superscripted plus sign indicates that only positive values of the parenthetical expression are considered. Figure 16D

Table 4 Single-Variate Models Applied to Utility Billing Data

Model Type	Independent Variable(s)	Form	Examples
One-parameter or constant (1-P)	None	$E = b_0$	Non-weather-sensitive demand
Two-parameter (2-P)	Temperature	$E = b_0 + b_1(T)$	
Three-parameter (3-P)	Degree-days/ Temperature	$E = b_0 + b_1(\mathrm{DD}_{BT})$ $E = b_0 + b_1(b_2 - T)^+$ $E = b_0 + b_1(T - b_2)^+$	Seasonal weather-sensitive use (fuel in winter, electricity in summer for cooling)
Four-parameter change point (4-P)	Temperature	$E = b_0 + b_1(b_3 - T)^+ - b_2(T - b_3)^+$ $E = b_0 - b_1(b_3 - T)^+ + b_2(T - b_3)^+$	Energy use in commercial buildings
Five-parameter (5-P)	Degree-days/ Monthly mean temperature	$E = b_0 - b_1(\mathrm{DD}_{TH}) + b_2(\mathrm{DD}_{TC})$ $E = b_0 + b_1(b_3 - T)^+ + b_2(T - b_4)^+$	Heating and cooling supplied by same meter

Note: DD denotes degree-days and T is monthly mean daily outdoor dry-bulb temperature.

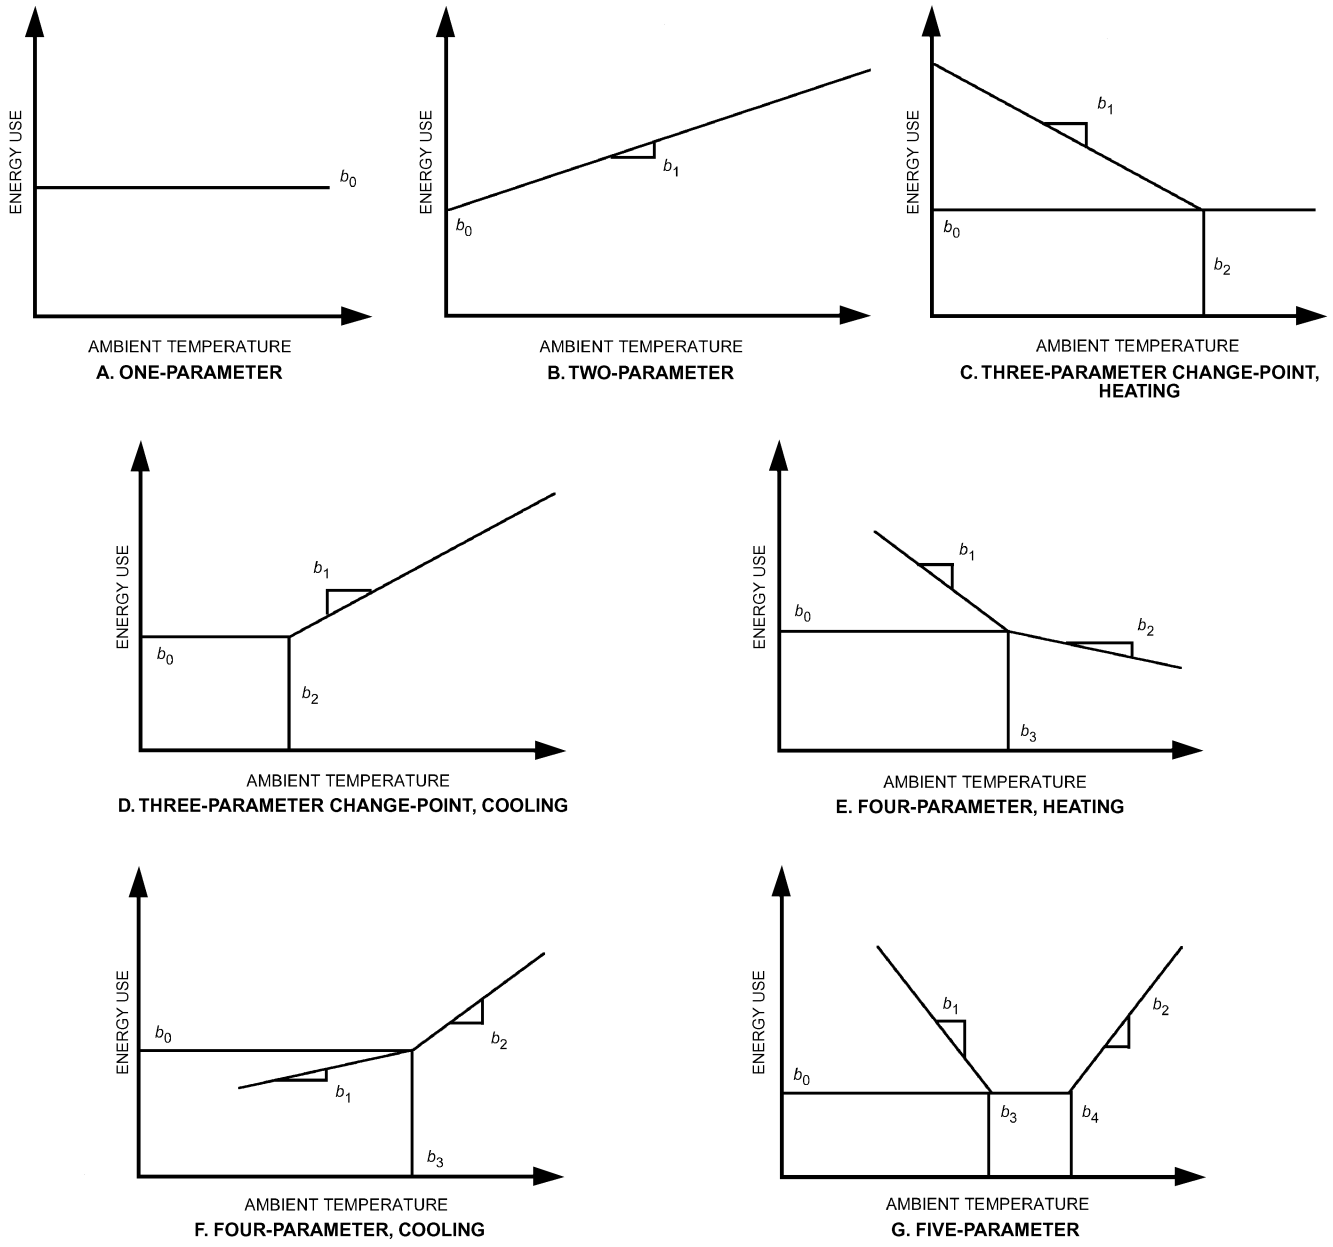

Fig. 16 Steady-State, Single-Variate Models for Modeling Energy Use in Residential and Commercial Buildings

shows a three-parameter model for cooling energy use, and Table 4 provides the appropriate analytic expression.

Figures 16E and 16F show four-parameter models for heating and cooling, respectively. The appropriate expressions for calculating the heating and cooling energy consumption are found in Table 4: b_0 represents the baseline energy exactly at the change point b_3, and b_1 and b_2 are the lower and upper region regression slopes for ambient air temperature below and above the change point b_3. Figure 16G shows a 5-P model (Fels 1986), which is useful for modeling buildings that are electrically heated and cooled. The 5-P model has two change points and a base level consumption value.

The advantage of these steady-state data-driven models is that their use can be easily automated and applied to large numbers of buildings where monthly utility billing data and average daily temperatures for the billing period are available. Steady-state single-variate data-driven models have also been applied with success to daily data (Kissock et al. 1998). In such a case, the variable-base degree-day method and monthly mean temperature models described previously for utility billing data analysis become identical in their functional form. Single-variate models can also be applied to daily data to compensate for differences such as weekday and weekend use by separating the data accordingly and identifying models for each period separately.

Disadvantages of steady-state single-variate data-driven models include insensitivity to dynamic effects (e.g., thermal mass) and to variables other than temperature (e.g., humidity and solar gain), and inappropriateness for some buildings (e.g., buildings with strong on/off schedule-dependent loads or buildings with multiple change points). Moreover, a single-variable, 3-P model such as the PRISM model (Fels 1986) has a physical basis only when energy use above a base level is linearly proportional to degree-days. This is a good approximation in the case of heating energy use in residential

Licensed for single user. © 2021, ASHRAE, Inc.

buildings where heating load never exceeds the heating system's capacity. However, commercial buildings generally have higher internal heat generation with simultaneous heating and cooling energy use and are strongly influenced by HVAC system type and control strategy. This makes energy use in commercial buildings less strongly influenced by outdoor air temperature alone. Therefore, it is not surprising that blind use of single-variate models has had mixed success at modeling energy use in commercial buildings (MacDonald and Wasserman 1989).

Change-point regression models work best with heating data from buildings with systems that have few or no part-load nonlinearities (i.e., systems that become less efficient as they begin to cycle on/off with part loads). In general, single-variate change-point regression models do not predict cooling loads as well because outdoor humidity has a large influence on latent loads on the cooling coil. Other factors that decrease the accuracy of change-point models include solar effects, thermal lags, and on/off HVAC schedules. A change point model based on a linear combination of temperature and specific humidity, and in which direct and diffuse irradiance were included as separate explanatory variables, was found to work well for aggregates of buildings (Ali et al. 2011).

Four-parameter models are a better statistical fit than three-parameter models in buildings with continuous, year-round cooling or heating (e.g., grocery stores and office buildings with high internal loads). However, every model should be checked to ensure that the regression does not falsely indicate an unreasonable relationship. Paulus et al. (2015) provided an algorithm aiding in the selection of change-point linear regression models.

A major advantage of using a steady-state data-driven model to evaluate the effectiveness of energy conservation retrofits is its ability to factor out year-to-year weather variations by using a normalized annual consumption (NAC) (Fels 1986). Basically, annual energy conservation savings can be calculated by comparing the difference obtained by multiplying the pre- and post-retrofit parameters by the weather conditions for the average year. Typically, 10 to 20 years of average daily weather data from a nearby weather service site are used to calculate 365 days of average weather conditions, which are then used to calculate the average pre- and post-retrofit conditions.

Utilities and government agencies have found it advantageous to prescreen many buildings against test regression models. These data-driven models can be used to develop comparative figures of merit for buildings in a similar standard industrial code (SIC) classification. A minimum goodness of fit is usually established that determines whether the monthly utility billing data are well fitted by the one-, two-, three-, four-, or five-parameter model being tested. Comparative figures of merit can then be determined by dividing the parameters by the conditioned floor area to yield average daily energy use per unit area of conditioned space. For example, an area-normalized comparison of base-level parameters across residential buildings would be used to analyze weather-independent energy use. This information can be used by energy auditors to focus their efforts on those systems needing assistance (Haberl and Komor 1990a, 1990b).

Multivariate Models. Three types of steady-state, multivariate models have been reported:

- **Standard multiple-linear** or **change-point regression models**, where the set of data observations is treated without retaining the time-series nature of the data (Katipamula et al. 1998).
- **Fourier series models** that retain the time-series nature of building energy use data and capture the diurnal and seasonal cycles according to which buildings are operated (Dhar 1995; Dhar et al. 1998, 1999a, 1999b; Seem and Braun 1991).
- **Gaussian process (GP) models** use a nonparametric, nonlinear regression method that produces estimates of the prediction uncertainty along with predictions of energy use (Burkhart et al. 2014; Heo and Zavala 2012; Heo et al. 2013).

These models are a logical extension of single-variate models, provided that the choice of variables to be included and their functional forms are based on the engineering principles under which HVAC and other building systems operate. The goal of modeling energy use by the multivariate approach is to characterize building energy use with a few readily available and reliable input variables. These input variables should be selected with care. The model should contain variables not affected by the retrofit and thus unlikely to change (e.g., climatic variables) from pre-retrofit to post-retrofit periods. Other less obvious variables, such as changes in operating hours, base load, and occupancy levels, should be included in the model if these are not energy conservation measures (ECMs) but variables that may change during the post-retrofit period.

Environmental variables that meet these criteria for modeling heating and cooling energy use include outdoor air dry-bulb temperature, solar radiation, and outdoor specific humidity. Some of these variables are difficult to estimate or measure in an actual building and hence are not good candidates for regressor variables. Further, some of the variables change little over time. Although the effect of these variables on energy use may be important, a data-driven model will implicitly lump their effect into the parameter that represents constant load. In commercial buildings, internally generated loads, such as the heat given off by people, lights, and electrical equipment, also affect heating and cooling energy use. These internal loads are difficult to measure in their entirety. However, monitored electricity used by internal lights and equipment may be a good surrogate for total internal sensible loads (Reddy et al. 1999). For example, when the building is fully occupied, it is also likely to be experiencing high internal electric loads, and vice versa.

The effect of environmental variables is important for buildings such as offices but may be less so for buildings with loads dominated by internal heat gain (e.g., data centers) and buildings with loads dominated by occupants (e.g. assembly buildings).

Differences in HVAC system behavior during occupied and unoccupied periods can be modeled by a dummy or indicator variable (Draper and Smith 1981). For some office buildings, there seems to be little need to include a dummy variable, but its inclusion in the general functional form adds flexibility.

Air-side heating and cooling use in various HVAC system types has been addressed by Reddy et al. (1995) and subsequently applied to monitored data in commercial buildings (Katipamula et al. 1994, 1998). Because quadratic and cross-product terms of engineering equations are not usually picked up by multivariate models, strictly linear energy use models are often the only option.

In addition to outdoor temperature T_o, internal electric equipment and lighting load E_{int}, solar loads q_{sol}, and latent effects via the outdoor dew-point temperature T_{dp} are candidate regressor variables. In commercial buildings, a major portion of the latent load derives from fresh air ventilation. However, this load appears only when the outdoor air dew-point temperature exceeds the cooling coil temperature. Hence, the term $(T_{dp} - T_s)^+$ (where the + sign indicates that the term is to be set to zero if negative, and T_s is the mean surface temperature of the cooling coil, typically about 11 to 13°C) is a more realistic descriptor of the latent loads than is T_{dp} alone. Using $(T_{dp} - T_s)^+$ as a regressor in the model is a simplification that seems to yield good accuracy.

Therefore, a multivariate linear regression model with an engineering basis has the following structure:

$$Q_{bldg} = b_0 + b_1(T_o - b_3)^- + b_2(T_o - b_3)^+ + b_4(T_{dp} - b_6)^- + b_5(T_{dp} - b_6)^+ + b_7 q_{sol} + b_8 E_{int} \quad (19)$$

Licensed for single user. © 2021, ASHRAE, Inc.

Based on the preceding discussion, $b_4 = 0$ because outdoor air does not introduce a latent cooling load when T_{dp} is less than the cooling coil surface temperature. Introducing indicator variable terminology (Draper and Smith 1981), Equation (19) becomes

$$Q_{bldg} = a + bT_o + cI + dIT_o + eT_{dp}^{+} + fq_{sol} + gE_{int} \quad (20)$$

where the indicator variable I is introduced to handle the change in slope of the energy use due to T_o. The variable I is set equal to 1 for T_o values to the right of the change point (i.e., for high T_o range) and set equal to 0 for low T_o values. As with the single-variate segmented models (i.e., 3-P and 4-P models), a search method is used to determine the change point that minimizes the total sum of squares of residuals (Fels 1986; Kissock et al. 1993).

Katipamula et al. (1994) found that Equation (20), appropriate for VAV systems, could be simplified for constant-volume HVAC systems:

$$Q_{bldg} = a + bT_o + eT_{dp}^{+} + fq_{sol} + gE_{int} \quad (21)$$

Note that instead of using $(T_{dp} - T_s)^+$, the absolute humidity potential $(W_0 - W_s)^+$ could also be used, where W_0 is the outdoor absolute humidity, and W_s is the absolute humidity level at the dew point of the cooling coil (typically about 0.009 kg/kg). A final aspect to keep in mind is that the term T_{dp}^{+} should be omitted from the regressor variable set when regressing heating energy use, because there are no latent loads on a heating coil.

These multivariate models are very accurate for daily time scales and slightly less so for hourly time scales. The inaccuracy at hourly time scales is because changes in the way the building is operated during the day and the night lead to different relative effects of the various regressors on energy use, which cannot be accurately modeled by one single hourly model. Breaking up energy use data into hourly bins corresponding to each hour of the day and then identifying 24 individual hourly models leads to appreciably greater accuracy (Katipamula et al. 1994).

Another accurate method uses a piecewise linear regression with respect to temperature and a time-of-week indicator variable to account for changes in energy use throughout each day of the week. This model (Matthieu 2011) may be applied to daily, hourly, or subhourly data.

Gaussian process (GP) models are nonparametric regression models, meaning the relationship between input and output variables is not strictly defined at the outset of the regression. In GP modeling, the measured output data are samples of a multivariate Gaussian distribution with the distribution parameters being the input variables. The distribution is defined by matching the covariance of the distribution to the covariance between the measured input and output data. For any new set of input variables, a Gaussian distribution is defined and the mean of the distribution is interpreted to be the predicted output and the variance of the distribution the uncertainty in the prediction. Thus, GP modeling not only produces an output value given a set of multivariate inputs, it also produces an estimate of the uncertainty of the prediction. Heo and Zavala (2012) used GP models to predict the hourly energy use of a chilled-water system using ambient temperature, occupancy, relative humidity, and chiller supply temperature and showed much better performance than standard multivariate regression models.

Hybrid Inverse Change Point Model. ASHRAE RP-1404 (Abushakra et al. 2014) was conducted primarily to develop analysis methodologies by which less than a whole year of field monitoring can be used for whole-building energy use prediction while satisfying current accuracy guidelines. The methodologies were developed to benefit ongoing efforts to spur diffusion of high-performance buildings by actual monitoring and to benefit energy service companies (ESCOs) and energy professionals who need a more cost-effective and acceptable alternative to year-long energy monitoring. Applications for the hybrid inverse change point model include detailed audits, green-building performance verification, and verification of post-retrofit claims using pre/post monitored data.

The modeling method is called *hybrid* because two regressions are performed at different time scales. The weather-dependent portion uses a year of monthly day-normalized utility bills, and the weather-independent portion uses either daily or hourly data covering a shorter time span, possibly as short as two weeks. The research revealed that (1) two weeks of hourly monitored data can be adequate for producing accurate long-term whole-building energy predictions, if the monitoring is taken at a correct time, and (2) adding more data to the regression model (extending the length of the short-term monitoring period) can, counterintuitively, make the predictive model poorer.

The analysis was completed in detail at two different time scales: daily and hourly. The analysis with both hourly and daily data revealed that the proper monitoring period is highly dependent on the time at which the data are taken, with the best time to collect data being during the spring and fall, or periods where the average temperature is close to the annual average temperature and the temperature has a wide range.

The following is an example of the modeling procedure that results in an hourly energy regression model. An example of the method applied to daily data can be found in Singh et al. (2013). The first regression uses one of the steady-state change point models shown in Figure 16 and Table 4, possibly with an additional weather-related independent variable, such as humidity. For example, the form could be a 3-P cooling shape (using the nomenclature of Table 4) such as

$$E_{daily} = b_0 + b_1(T_{daily\ average} - b_2)^+ \quad (22)$$

where E_{daily} is day-normalized energy consumption in units of energy consumption per day.

For predicting cooling thermal loads, such as chilled-water use, investigate adding the outdoor humidity variable as a regressor in the model to account for latent loads. Equation (22) would become a multivariable linear regression of the form

$$E_{daily} = b_0 + b_1(T_{daily\ average} - b_2)^+ + b_3(\omega_{daily\ average} - 0.009)^+ \quad (23)$$

The $(\omega_{daily\ average} - 0.009)^+$ term in Equation (23) is a surrogate for the latent load existing only when the absolute humidity ratio of air entering the cooling coil is above 0.009.

The dependent variable for the second regression is the residuals resulting from using the first equation to predict the temperature dependent energy portion at the hourly time scale, calculated by dividing the temperature dependent portion of the first regression by 24 hours/day. The second regression uses gathered hourly data consisting of weather and an internal driving variable(s), such as $X_{internal,hourly}$, often an occupancy indicator or submetered lighting and equipment load. The second regression is then performed to calculate the coefficients for the internal driving variables and constant term. Using Equation (22), the second regression has the form

$$E_{hourly} - \frac{b_1}{24}(T_{hourly} - b_2)^+ = b_3 + b_4(X_{internal,\,hourly}) \quad (24)$$

The final equation for prediction at the hourly time scale is a rearrangement of Equation (24).

$$E_{hourly} = b_3 + \frac{b_1}{24}(T_{hourly} - b_2)^+ + b_4(X_{internal,\,hourly}) \quad (25)$$

Polynomial Models. Historically, polynomial models have been widely used as pure statistical models to model the behavior of equipment such as pumps, fans, and chillers (Stoecker and Jones 1982), as discussed in the section on HVAC Component Modeling. The theoretical aspects of calculating pump performance are well understood and documented. Pump capacity and efficiency are calculated from measurements of pump pressure, flow rate, and pump electrical power input. Phelan et al. (1996) studied the predictive ability of linear and quadratic models for electricity consumed by pumps and water mass flow rate, and concluded that quadratic models are superior to linear models. For fans, Phelan et al. (1996) studied the predictive ability of linear and quadratic polynomial single-variate models of fan electricity consumption as a function of supply air mass flow rate, and concluded that, although quadratic models are superior in terms of predicting energy use, the linear model seems to be the better overall predictor of both energy use and demand (i.e., maximum monthly power consumed by the fan). This is a noteworthy conclusion given that a third-order polynomial is warranted analytically as well as from monitored field data presented by previous authors [e.g., Englander and Norford (1992), Lorenzetti and Norford (1993)].

Polynomial models have been used to correlate chiller (or heat pump) capacity Q_{evap} and the electrical power consumed by the chiller (or compressor) E_{comp} with the relevant number of influential physical parameters. For example, based on the functional form of the DOE-2 building simulation software (York and Cappiello 1982), models for part-load performance of energy equipment and plant, E_{comp}, can be modeled as the following triquadratic polynomial:

$$\begin{aligned} E_{comp} = {} & a + bQ_{evap} + cT_{cond}^{in} + dT_{evap}^{out} + eQ_{evap}^2 \\ & + fT_{cond}^{in\,2} + gT_{evap}^{out\,2} + hQ_{evap}T_{cond}^{in} + iT_{evap}^{out}Q_{evap} \\ & + jT_{cond}^{in}T_{evap}^{out} + kQ_{evap}T_{cond}^{in}T_{evap}^{out} \end{aligned} \quad (26)$$

In this model, there are 11 model parameters to identify. However, because all of them are unlikely to be statistically significant, a step-wise regression to the sample data set yields the optimal set of parameters to retain in a given model. For example, Armstrong et al. (2006b) found the b, i, and k terms, using T_{odb} for T_{cond} and T_{ewb} for T_{evap}, to provide an adequate model of three different fixed-speed rooftop units. Other authors, such as Braun (1992) and Hydeman et al. (2002), used slightly different polynomial forms. Over a wide range of capacity and lift a full tricubic polynomial can be justified for VRF heat pump equipment (Gayeski et al. 2011).

Physical Models. In contrast to polynomial models, which have no physical basis, physical models are based on fundamental thermodynamic or heat transfer considerations. These types of models are usually associated with the parameter estimation approach. Often, physical models are preferred because they generally have fewer parameters, and their mathematical formulation can be traced to actual physical principles that govern the performance of the building or equipment. Hence, model coefficients tend to be more robust, leading to sounder model predictions. Only a few studies have used steady-state physical models for parameter estimation relating to commercial building energy use [e.g., Reddy et al. (1999)]. Unlike in single-family residences, it is difficult to perform elaborately planned experiments in large buildings and obtain representative values of indoor fluctuations.

For example, the generalized Gordon and Ng (GN) model (Gordon and Ng 2000) is a simple, analytical, universal model for chiller performance based on first principles of thermodynamics and linearized heat losses. The model predicts the dependent chiller coefficient of performance (COP) (the ratio of thermal cooling capacity Q_{ch} to electrical power E consumed by the chiller) with easily measurable parameters such as the fluid (water or air) temperature entering the condenser T_{cdi}, fluid temperature entering the evaporator T_{chi}, and the thermal cooling capacity of the evaporator. The GN model is a three-parameter model in the following form:

$$\left(\frac{1}{\text{COP}} + 1\right)\frac{T_{chi}}{T_{cdi}} - 1 = a_1\frac{T_{chi}}{Q_{ch}} + a_2\frac{(T_{cdi} - T_{chi})}{T_{cdi}Q_{ch}} + a_3\frac{(1/\text{COP} + 1)Q_{ch}}{T_{cdi}} \quad (27a)$$

where temperatures are in absolute units.

Substituting the following,

$$x_1 = \frac{T_{chi}}{Q_{ch}} \qquad x_2 = \frac{(T_{cdi} - T_{chi})}{T_{cdi}Q_{ch}} \qquad x_3 = \frac{(1/\text{COP} + 1)Q_{ch}}{T_{cdi}} \quad (27b)$$

and

$$y = \left(\frac{1}{\text{COP}} + 1\right)\frac{T_{chi}}{T_{cdi}} - 1$$

the model given by Equation (27a) becomes

$$y = a_1x_1 + a_2x_2 + a_3x_3 \quad (27c)$$

which is a three-parameter linear model with no intercept term. The parameters of the model in Equation (27c) have the following physical meaning:

$a_1 = \Delta S$ = total internal entropy production in chiller

$a_2 = Q_{leak}$ = heat losses (or gains) from (or into) chiller

$a_3 = R$ = total heat exchanger thermal resistance = $1/C_{cd} + 1/C_{ch}$, where C is effective thermal conductance

Gordon and Ng (2000) point out that Q_{leak} is typically an order of magnitude smaller than the other terms, but it is not negligible for accurate modeling, and should be retained in the model if the other two parameters identified are to be used for chiller diagnostics. The same linear model structure as Equation (27c) can be used if the fluid temperature leaving the evaporator T_{cho} is used instead of T_{chi}. However, the physical interpretation of the term a_3 is modified accordingly.

Reddy and Anderson (2002) and Sreedharan and Haves (2001) found that the GN and multivariate polynomial (MP) models were comparable in their predictive abilities. The GN model requires much less data if selected judiciously [even four well-chosen data points can yield accurate models, as demonstrated by Corcoran and Reddy (2003)]. Jiang and Reddy (2003) tested the GN model against more than 50 data sets covering various generic types and sizes of water-cooled chillers (single- and double-stage centrifugal chillers with inlet guide vanes and variable-speed drives, screw, scroll), and found excellent predictive ability (coefficient of variation of RMSE in the range of 2 to 5%).

Dynamic Models

In contrast to steady-state data-driven models, which are used with monthly and daily data containing one or more independent variables, dynamic data-driven models are typically used with hourly or subhourly data in cases where the building's thermal mass is significant enough to delay heat gains or losses. Dynamic models traditionally require solving a set of differential equations. Disadvantages of dynamic data-driven models include their complexity and the need for more detailed measurements to tune the model. Unlike steady-state data-driven models, dynamic data-driven models usually require a high degree of user interaction and knowledge of the building or system being modeled.

Licensed for single user. © 2021, ASHRAE, Inc.

Several residential energy studies have used dynamic data-driven models based on parameter estimation approaches, usually involving intrusive data gathering. Rabl (1988) classified the various types of dynamic data-driven models used for whole-building energy use, and identified the common underlying features of these models. There are essentially four different types of model formulations: thermal network, time series, differential equation, and modal, all of which qualify as parameter-estimation approaches.

A few studies (Hammarsten 1984; Rabl 1988; Reddy 1989) evaluated these different approaches with the same data set. Several papers reported results of applying different techniques, such as thermal network and autoregressive-moving-average (ARMA) models, to residential and commercial building energy use. Examples of dynamic data-driven models for commercial buildings are found in Andersen and Brandemuehl (1992), Braun (1990), and Rabl (1988), and for apartment buildings in Armstrong et al. (2006a). Successful use of ARMA models for model-predictive control is reported by Gayeski et al. (2012).

Dynamic data-driven models based on pure statistical approaches have also been reported. Two examples are machine learning (Miller and Seem 1991) and artificial neural networks (Kreider and Haberl 1994; Kreider and Wang 1991; Miller and Seem 1991).

6.3 MODEL ACCURACY AND GOODNESS OF FIT

Good data-driven models are determined by their overall goodness-of-fit and accuracy metrics, by testing each parameter for significance, and ensuring that the chosen model form and regressors explain the response of the dependent variable as completely as possible.

Accuracy of model results may be represented by statistical metrics. Commonly used metrics are the normalized mean bias error (NMBE) and the coefficient of variance of the root mean square error [CV(RMSE)]. Equations for these metrics are provided in the section on Modeling Calibration. CV(RMSE) tests how well the model recreates the data and is also an indication of random error. NMBE tests how biased the model is in predicting outputs over the period the model was developed.

A widely used statistic to gage a model's goodness of fit is the **coefficient of determination R^2** (Draper and Smith 1981; Neter et al. 1989). A value of $R^2 = 1$ indicates a perfect correlation between actual data and the regression equation; a value of $R^2 = 0$ indicates no correlation. For tuning for a performance contract, a rule of thumb is that the value of R^2 should not be less than 0.75.

When more than one independent variable is included in the regression, the adjusted R^2 should be used to assess the goodness of fit, as the unadjusted R^2 increases with the addition of variables, and can be misleading. When additional independent variables are included, each should be tested for significance. The standard error of the estimate of the coefficients on each independent variable should be assessed. The smaller the standard error compared to the coefficient's magnitude, the more reliable the coefficient estimate. To identify the significance of individual coefficients, ***t*-statistics** (or ***t*-values**) are used. These are simply the ratio of the coefficient estimate divided by the standard error of the estimate.

The coefficient of each variable included in the regression has a *t*-statistic. For a coefficient to be statistically meaningful, the absolute value of its *t*-statistic must be at least 2.0. In other words, under no circumstances should a variable be included in a regression if the standard error of its coefficient estimate is greater than half the magnitude of the coefficient (even when including a variable that increases the adjusted R^2). Generally, including more variables in a regression increases R^2, but the significance of most individual coefficients is likely to decrease.

Some independent variables may be linearly correlated. This condition, called **multicollinearity**, can result in large uncertainty in the estimates of the regression coefficients (i.e., error) and can also lead to poorer model prediction accuracy compared to a model where the regressors are not linearly correlated.

Residuals should be plotted against each independent variable to check that no relationship of any sort (not just linear correlation) exists. The distribution of residuals should follow a normal distribution. For time-series data, the residuals should be checked for serial correlation (ASHRAE 2010).

Several authors recommend using **principal component analysis (PCA)** to overcome multicollinearity effects. PCA was one of the strongest analysis methods in the ASHRAE Predictor Shootout I and II contests (Haberl and Thamilseran 1996; Kreider and Haberl 1994). Analysis of multiyear monitored daily energy use in a grocery store found a clear superiority of PCA over multivariate regression models (Ruch et al. 1993), but this conclusion is unsupported for commercial building energy use in general. A more general evaluation by Reddy and Claridge (1994) of both analysis techniques using synthetic data from four different U.S. locations found that injudicious use of PCA may exacerbate rather than overcome problems associated with multicollinearity. Draper and Smith (1981) also caution against indiscriminate use of PCA.

6.4 EXAMPLES USING DATA-DRIVEN METHODS

Modeling Utility Bill Data

The following example (taken from Sonderegger 1998) illustrates a utility bill analysis. Assume that values of utility bills over an entire year have been measured. To obtain the equation coefficients through regression, the utility bills must be normalized by the length of the time interval between utility bills. This is equivalent to expressing all utility bills, degree-days, and other independent variables by their daily averages.

Appropriate modeling software is used in which values are assumed for heating and cooling balance points; from these, the corresponding heating and cooling degree-days for each utility bill period are determined. Repeated regression is done till the regression equation represents the best fit to the meter data. The model coefficients are then assumed to be tuned. Some programs allow direct determination of these optimal model parameters (e.g., balance point temperature) without manual tuning of the parameters by the user.

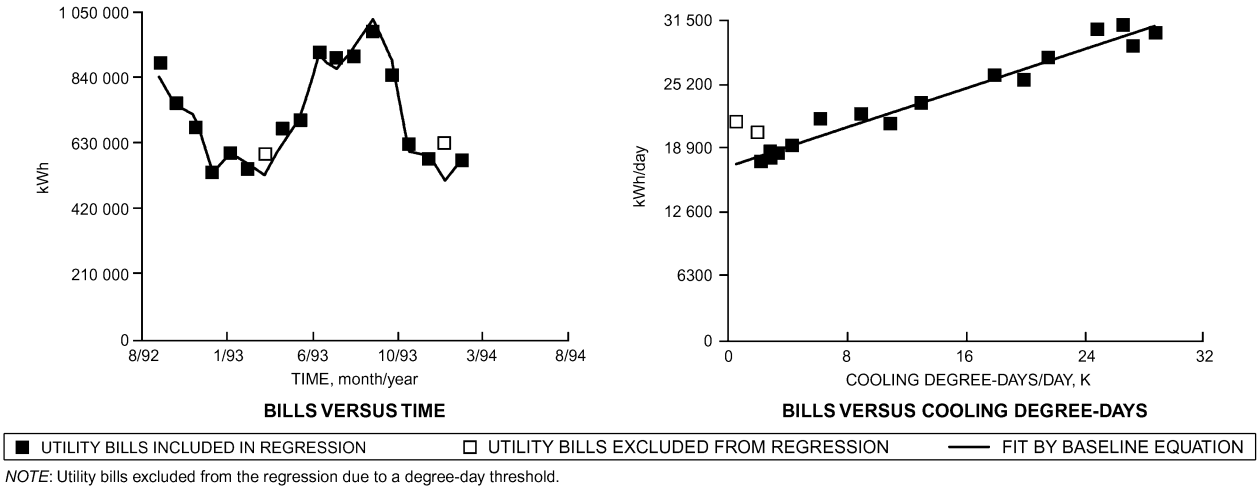

Figure 17 shows how well a regression fit captures measured baseline energy use in a hospital building. Cooling degree-days are found to be a significant variable, with the best fit for a base temperature of 12.2°C.

In this analysis, some individual utility bills may be unsuitable to develop a baseline and should be excluded from the regression. For example, a bill may be atypically high because of a one-time equipment malfunction that was subsequently repaired. Given the justification to exclude some data, it is often tempting to look for more reasons to exclude bills that fall far from "the line" and not question those that are close to it. For example, bills for periods containing vacations or production shutdowns may look anomalously low, but excluding them from the regression would result in a chronic overestimate of the future baseline during the same period.

Neural Network Models

Figure 18 shows results for a single neural network typical of several hundred networks constructed for an academic engineering center located in central Texas. The cooling load is created by solar gains, internal gains, outdoor air sensible heat, and outdoor air humidity loads. The neural network is used to predict the pre-retrofit energy consumption for comparison with measured consumption of the retrofitted building. Six months of pre-retrofit data were available to train the network. Solid lines show the known building consumption data, and dashed lines show the neural network

NOTE: Utility bills excluded from the regression due to a degree-day threshold.

Fig. 17 Variable-Base Degree-Day Model Identification Using Electricity Utility Bills at Hospital
(Sonderegger 1998)

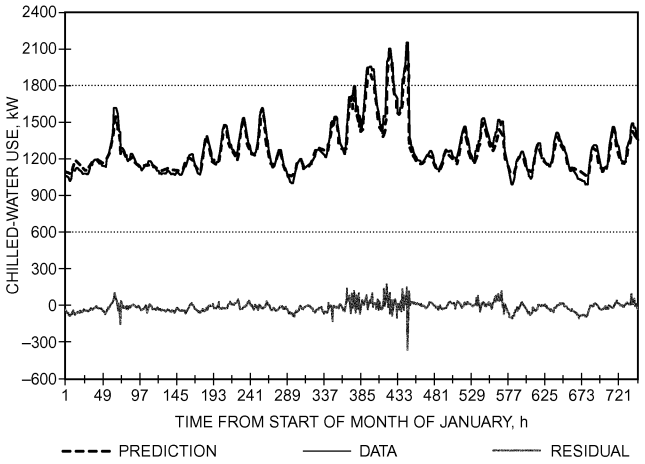

Fig. 18 Neural Network Prediction of Whole-Building, Hourly Chilled-Water Consumption for Commercial Building

predictions. This figure shows that a neural network trained for one period (September 1989) can predict energy consumption well into the future (in this case, January 1990).

The network used for this prediction had two hidden layers. The input layer contained eight neurons that receive eight different types of input data as listed below. The output layer consisted of one neuron that gave the output datum (chilled-water consumption). Each training fact (i.e., training data set), therefore, contained eight input data (independent variables) and one pattern datum (dependent variable). The following eight hourly input data used in each hour's data vector were selected on physical bases (Kreider and Rabl 1994):

- Hour number (0 to 2300)
- Ambient dry-bulb temperature
- Horizontal insolation
- Humidity ratio
- Wind speed
- Weekday/weekend binary flag (0, 1)
- Past hour's chilled-water consumption
- Second past hour's chilled-water consumption

These measured independent variables were able to predict chilled-water use to an RMS error of less than 4% (JCEM 1992).

Choosing an optimal network's configuration for a given problem remains an art. The number of hidden neurons and layers must be sufficient to meet the requirement of the given application. However, if too many neurons and layers are used, the network tends to memorize data rather than learning (i.e., finding the underlying patterns in the data). Further, choosing an excessively large number of hidden layers significantly increases the required training time for certain learning algorithms. Anstett and Kreider (1993), Krarti et al. (1998), Kreider and Wang (1991), and Wang and Kreider (1992) report additional case studies for commercial buildings.

6.5 MODEL SELECTION

Table 5 presents a decision diagram for selecting a forward or data-driven model where use of the model, degree of difficulty in understanding and applying the model, time scale for data used by the model, calculation time, and input variables used by the models are the criteria used to choose a particular model.

More information on data-driven models can be found in the ASHRAE *Inverse Modeling Toolkit* (Haberl and Cho 2004; Haberl et al. 2003; Kissock et al. 2003). This toolkit contains FORTRAN 90 and executable code for performing linear and change-point linear regressions, variable-based degree-days, multilinear regression, and combined regressions. It also includes a complete test suite of data sets for testing all models.

7. MODEL CALIBRATION

Calibration is the use of known data (e.g., utility bills) on the observed relationship between a dependent variable (e.g., simulation output) and an independent variable (e.g., simulation input) to make estimates of other values of the independent variable from new observations of the dependent variable. For energy simulation models, calibration typically involves observation of changes in simulation output as simulation inputs are modified, with the goal of identifying a set of inputs leading to simulation outputs that match measured building performance.

The perception of validity and usefulness of any energy simulation model is largely determined by how closely the simulation output matches actual building performance, usually in terms of energy consumption. The process of calibrating a model to match actual

performance can be a complex and time-consuming endeavor. Identifying and isolating sources of discrepancy between the results of a model and actual data are not always possible, as described in the section on Uncertainty in Modeling. In addition, energy model calibration typically involves several input parameters that must be calibrated using a relatively limited amount of measured data; because of combinatorial complexity, calibration is an underdetermined system in which there can exist many unique (and substantially different) models that are within a tolerable error.

A typical calibration requires an initial model, set of inputs to be calibrated, weather data, collection of measurements, error metric, and acceptance criteria. Once defined, a manual, semiautomatic, or automatic calibration process is invoked on these requirements. In some cases, there is a validation process afterward to assess how well the calibration process performed. Analytical, mathematical, or statistical techniques can be used for the calibration process or to assess the quality of calibration. Table 6 lists some of the common methods and techniques used for model calibration (Coakley et al. 2014). These methods have varying degrees of complexity and result in varying degrees of calibration accuracy.

The quality of a calibration is often evaluated in terms of statistical indicators that quantify discrepancies between the model output and measured output. These metrics are based on time steps, and it may be the case that a model calibrated to low-resolution (e.g., monthly) whole-building data is highly inaccurate when compared to higher-resolution temporal (e.g., hourly) or spatial (e.g., level of a thermal zone) data. Among statistical indicators, the normalized mean bias error (NMBE) and the coefficient of variance of the root mean square error [CV(RMSE)], Equations (28) and (29) respectively, are widely used. In these equations, the values are summed for each time step (e.g., monthly or hourly values) over the course of an evaluation period (e.g., year), and the parameter V is the building performance variable under consideration (usually monthly whole-building energy consumption):

$$\text{NMBE} = \frac{\sum(V_{actual} - V_{modeled})}{(N-1) \times \text{Mean}(V_{actual})} \times 100\% \quad (28)$$

$$\text{CV(RMSE)} = \frac{\sqrt{\frac{\sum(V_{actual} - V_{modeled})^2}{N-1}}}{\text{Mean}(V_{actual})} \times 100\% \quad (29)$$

where

V_{actual} = parameter's measured or metered value for each time step (e.g. month)
$V_{modeled}$ = parameter's estimated or modeled value for each time step
N = number of time steps being analyzed during period of evaluation

ASHRAE *Guideline* 14-2014 states that a model can be considered calibrated if NMBE < 5% and CV(RMSE) < 15% when monthly data are used, or NMBE < 10% and CV(RMSE) < 30% when hourly data are used. Because CV(RMSE) is the positive average sum-squared error divided by the actual mean, it can be considered the percent error between the simulation and measured data. Because NMBE is a signed error divided by the mean, it indicates bias percent for under- (NMBE > 0) or overshooting (NMBE < 0) the actual data during the period of evaluation.

Additional resources and tools useful for energy model calibration include ASHRAE RP-1051 (Reddy 2006), ASHRAE RP-1093 (Abushakra et al. 2000), and NREL *Technical Report* 5500-60127 (Robertson 2013).

The main challenges of manual model calibration are that it is labor intensive and time consuming, it requires a high level of user skill and knowledge in both simulation and practical building operation, and the results often vary with the individual performing the calibration. Several practical difficulties prevent achieving a calibrated simulation or a simulation that closely reflects actual building performance, including (1) measurement and adaptation of weather data for use by simulation programs (e.g., converting global horizontal solar into beam and diffuse solar radiation), (2) collecting reliable actual meteorological year data for a specific building during the type period in which energy-use data was collected (Bhandari et al. 2012), (3) choice of methods used to calibrate the model, and (4) choice of methods used to measure required input parameters for the simulation (i.e., building mass, infiltration coefficients, and shading coefficients). Calibrated models typically involve a large number of input parameters to be calibrated, a high degree of expertise, multiple iterations, and substantial computing time. Every model, calibrated or not, carries assumptions and simplifications that are often deemed reasonable, but should be reevaluated when the model is used for different purposes. Bou-Saada and Haberl (1995a, 1995b), Bronson et al. (1992), Corson (1992), Garrett and New (2014), Haberl and Bou-Saada (1998), Kaplan et al. (1990), Liu and Liu (2011), Manke et al. (1996), Monfet et al. (2009), Norford et al. (1994), O'Neill et al. (2011), Reddy (2006, 2011), Reddy and Maor (2006), Reddy et al. (2007a, 2007b), Song and Haberl (2008a, 2008b), and Sun et al. (2016) provide examples of different methods used to calibrate

Table 6 Calibration Methods and Techniques

Method/Technique	Description
Detailed audit	Detailed audits are often conducted before building model development to gain a better knowledge of the building systems and characteristics (e.g., geometry, HVAC systems, lighting, equipment, occupancy schedules).
Expert knowledge/templates/ model database	Approaches that use • Expert knowledge or judgment as a key element of the process • Prior definition of typical building templates • Database of typical building parameters and components to reduce the requirement for user inputs during model development
Intrusive testing	Intrusive techniques require some intervention in operation of the actual building, such a "blink tests," whereby groups of end-use loads (e.g., plug loads, lighting) are turned on and off in a controlled sequence to determine their overall effect on the baseline building load.
High-resolution ("high-res") data	Data are recorded at hourly (or subhourly) levels as opposed to using daily load profiles or monthly utility bill data.
Short-term energy monitoring	Metering equipment is used to record on-site measurements for a short period of time (e.g., two weeks). This may be used in identifying typical energy end-use profiles and/or base loads.
Graphical comparison	Two- or three-dimensional plots are used to aid comparison of measured and simulated data in a way that can inform manual calibration. Whereas 2D scatterplots are frequently used, 3D techniques can allow effective visualization of larger quantities of data.
Signature analysis	Signature analysis techniques are a specific type of graphical analysis technique, typically used by HVAC simulation engineers to identify faulty parameters in air-handling unit (AHU) simulation. They may also be used to develop optimized operation and control schedules. Signature analysis methods are commonly used for the calibration of models based on the simplified energy analysis procedure (SEAP).
Statistical displays	Graphical representation of statistical indices and comparisons can facilitate intuitive interpretation for calibration. This includes data comparison techniques such as carpet plots, box-whisker-mean (BWM) plots, and monthly percent difference time-series graphs.
Base case modeling	The base case model refers to the use of measured base loads to calibrate the building model. Base loads refer to minimum, or weather independent, electrical and gas energy consumption. Calibration is carried out during the base case when heating and cooling loads are minimal and the building is dominated by internal loads, thus minimizing impact of weather dependent variables.
Model parameter estimation	Deduction of overall aggregate (or lumped) parameters (e.g., U-factors) using nonintrusive, measured data.
Parameter reduction	This involves reducing the requirement for detailed input for variable schedules (e.g., plug loads, lighting, occupancy, equipment). Day typing is one such approach, which works by analyzing long-term data and reducing this to manageable typical day-type schedules (e.g., weekdays versus weekends, winter versus summer). Zone typing may also be used to reduce large models into similar thermal zones (e.g., core, perimeter, offices, unoccupied spaces).
Data disaggregation	Data disaggregation refers to the application of nonintrusive load monitoring (NILM) techniques to decouple multiple derived data streams (e.g., lighting, miscellaneous plug loads) from a single measured data stream (e.g. whole-building electrical energy consumption).
Evidence-based model development	Evidence-based approaches may be described as those that implement a procedural approach to model development, making changes according to source evidence rather than ad hoc intervention. Strictly, this approach should account for adjustments to model parameters in a structured fashion (e.g., using version control software).
Sensitivity analysis	Sensitivity analysis procedures may be used in some studies to assess the influence of input parameters on model predictions. This information may be used to identify important parameters for measurement, calibration, or detailed investigation.
Uncertainty quantification	Parameter uncertainty may be used to directly assist in model calibration or provide a basis for quantification of risk propagation to the results (e.g., uncertainty-related risk in energy conservation measure analysis).
Bayesian calibration	Bayesian calibration is an alternative statistical approach to model calibration. The approach offers the advantage of naturally accounting for uncertainty in model prediction using prior input distributions.
Pattern-based approach	A process to calibrate energy models using patterns of monthly simulated and measured energy consumption using pattern fit criteria.
Multiobjective optimization	Most automated calibration techniques use a single- or multiobjective optimization function to reduce the difference between measured and simulated data. An objective function may be used to set a target of minimizing, for example, the mean square error between measured data and simulation output. Conversely, a penalty function may also be used to reduce the likelihood of deviating too far from the default value for a parameter.

simulation models. A methodology for testing calibration methods is described in the section on Model Validation and Testing.

Calibration techniques can be roughly classified as either manual or automated methods. Manual calibration methods include graphical analysis and sensitivity analysis. Examples of methods used for automated calibration include Bayesian analysis, pattern matching, and multiobjective optimization.

Manual calibration is an iterative approach that can be labor intensive and involves separate manipulation of individual parameters. This approach involves using an existing building simulation model and "tuning" or calibrating the various input parameters so that simulation program output matches with observed energy use. Calibration can be performed using data from any time period (e.g., monthly, or only a few weeks over the year), but the final calibrated model is likely to be less accurate when fewer data are used during the calibration process. Hourly monitored energy data (most compatible with the time step adopted by most building energy simulation programs) can allow development of more accurate calibrated models, but calibrators often work without hourly data.

During the manual calibration process, graphical representations and/or statistics comparing modeled data to measured data are displayed in an attempt to elucidate the value that input parameters could be set to in order to improve the match between simulation output and measured data. Calibrators often use sensitivity analyses to focus calibration efforts on the parameters that make the biggest difference in terms of energy use. In contrast to manual calibration, automated techniques use mathematical, algorithmic techniques implemented as computer software. Bayesian analysis, pattern-based

calibration, and multiobjective optimization are methods used for automated calibration.

7.1 BAYESIAN ANALYSIS

This approach uses a theorem originally proposed by Thomas Bayes, an English statistician (1701-1761). Bayesian analysis provides an updated, more refined (more accurate) model based on the model from the prior iteration and a likelihood function derived from a statistical model for the measured data. Individual parameters with varying degrees of uncertainty can be analyzed to predict the range of values for that parameter, and its most likely value. In most Bayesian analyses, the formulation of the likelihood function is based on the work of Kennedy and O'Hagan (2001).

Riddle and Muehleisen (2014) stated that, although Bayesian analysis can initially seem overwhelming, this method of calibration does not rely on extensive expertise. They further stated that this method provides an automated process for optimizing parameter values while accounting for multiple sources of uncertainty. Heo (2011) suggested that there are three primary strengths with Bayesian analysis: (1) it improves the reliability of a model by tuning important uncertain parameters in the model to represent actual building operations, (2) it results in calibrated models that are suitable to uncertainty analysis, and (3) the calibration procedure objectively quantifies uncertainty through the determination of a set of calibration parameters prioritized by their importance to the model outcome.

7.2 PATTERN-BASED APPROACH

This approach (Sun et al. 2016) automates a process to calibrate energy models using patterns of monthly simulated and measured energy use. The process contains four key steps: (1) running the original precalibrated energy model to obtain monthly simulated electricity and gas use; (2) establishing a pattern bias, either universal or seasonal, by comparing load shape patterns of simulated and actual monthly energy use; (3) using programmed logic to select which parameter to tune first based on bias pattern, weather, and input parameter interactions; and (4) automatically tuning the calibration parameters and checking the progress using pattern-fit criteria.

The automated calibration algorithm was implemented in the Commercial Building Energy Saver (Hong et al. 2015), a web-based building energy retrofit analysis toolkit. The novelty of the developed calibration methodology lies in linking parameter tuning with the underlying logic associated with bias pattern identification. Although there are some limitations (e.g., coverage of building and system types) to the current implementation, the pattern-based automated calibration methodology can be universally adopted as an alternative to manual or hierarchical calibration approaches.

7.3 MULTIOBJECTIVE OPTIMIZATION

This approach uses the well-established field of mathematical optimization to select the best value of an input parameter, from some set of available alternatives, with regard to a fitness function. Standard optimization can be used when a single fitness criterion (e.g., whole-building energy use) is considered, and multiobjective optimization can be used to evaluate any number of building performance criteria (e.g., submetering, temperatures, relative humidity, heat flux) for which a user may have measured data. This class of algorithms is advantageous in that it is fully automated, can calibrate hundreds of (uncertain) input parameters, and is simulation-engine-agnostic (i.e., it can apply to any simulation/software that has inputs and generates outputs comparable to measured data). Optimization algorithms can also accommodate more intensive submetering expected in the future, because fitness functions can compare calibration performance to either monthly (12), hourly (8760), or submetered, subhourly (1,000,000+) data points in less than a second. The disadvantage is that these algorithms, by themselves, do not capture the sense-making common of human calibrators and could thus generate physically unrealistic models that may not even simulate.

A method of comparing these techniques was defined (New et. al 2012), studied (Edwards 2013), and evaluated (Sanyal 2014), as defined in the section on Testing Model Calibration Techniques Using Synthetic Data, to determine (Garrett and New 2014) the best algorithm, of those tested, for calibration. In terms of robustness, speed, and calibration accuracy over a 20,000 building calibration study, the best algorithm was an evolutionary algorithm known as the nondominated sorting genetic algorithm (NSGA-II) (Deb et al. 2002). Optimal values for NSGA-II, mechanisms for speedup, and methods to mitigate limitations regarding physical realism were identified for the traditional use cases of calibrating to monthly (Garret et al. 2013) and hourly (Garrett and New 2015) whole-building electrical data before being made publicly available (New 2016).

Table 7 ANSI/ASHRAE *Standard* 140 Validation Test Matrix

Test Type/ Model Type	Building Thermal Fabric (Basic Building Physics)[a]	Mechanical Equipment and On-Site Energy Generation Equipment[a]
Analytical verification	Ground-Coupled Heat Transfer BESTEST for Slab On Grade (5.2.4)	HVAC BESTEST Volume 1 (5.3)
		Gas-Forced Air Furnace BESTEST (5.4.1, 5.4.2)

[b]Anticipated as Addendum a to *Standard* 140-2014 in 2017.

8. VALIDATION AND TESTING

ANSI/ASHRAE *Standard* 140 was developed to identify and diagnose differences in predictions that may be caused by algorithmic differences, modeling limitations, faulty coding, or input errors. The methodological structure of *Standard* 140 allows all elements of a complete validation approach to be added as they become available. Table 7 shows the structure and the test suites in *Standard* 140-2014.

The table is an abbreviated way of representing the parameter space in which building energy simulation programs operate. Each cell in the matrix represents a large region in the space, so listing a test suite in a cell does not obviate the need for additional suites in that cell, and tests are needed in the empty cells. Class 1 tests in section 5 of the standard are based on procedures developed by the National Renewable Energy Laboratory (NREL) and field-tested by the International Energy Agency (IEA) over three IEA research tasks (Judkoff and Neymark 1995a; Neymark and Judkoff 2002, 2004). An additional section 5 test suite, which follows NREL's methodology, was developed by Natural Resources Canada (Purdy and Beausoleil-Morrison 2003). Class 2 tests (section 7 of the standard) are based on procedures developed by NREL and field tested by the Home Energy Rating Systems (HERS) Council Technical Committee (Judkoff and Neymark 1995b). Additional tests not yet in

Table 8 Validation Techniques

Technique	Advantages	Disadvantages
Empirical validation (test of model and solution process)	• Approximate truth standard within experimental accuracy • Any level of complexity	• Experimental uncertainties: • Instrument calibration, spatial/temporal discretization • Instrumentation can alter the effect being measured • Imperfect knowledge/specification of experimental object (building) being simulated • High-quality, detailed measurements are expensive and time consuming • Only a limited number of test cases are practical • Diagnostics can be difficult • Requires empirical determination of inputs • Only a limited number of sensitivity test cases are practical
Analytical verification (test of solution process)	• No input uncertainty • Exact mathematical or secondary mathematical truth standard for given model • Inexpensive	• No test of model validity or suitability • Limited to highly constrained cases for which analytical or quasi-analytical solutions can be developed*
Comparative testing (relative test of model and solution process)	• No input uncertainty • Any level of complexity • Many diagnostic comparisons possible • Inexpensive and quick	• No absolute truth standard (only statistically based acceptance ranges are possible)

Source: Judkoff and Neymark (2006).
*Use of verified numerical solutions can extend the analytical verification approach to more realistic cases (Neymark et al. 2008).

Standard 140 were developed under ASHRAE research projects (Spitler et al. 2001; Yuill and Haberl 2002; Yuill et al. 2006), and under joint IEA Solar Heating and Cooling Programme/Energy Conservation in Buildings and Community Systems Task 34/Annex 43 (Judkoff and Neymark 2009); these may further populate the validation test matrix in the future. *Standard* 140 is cited by a number of codes, standards, and regulatory bodies, including ASHRAE *Standard* 90.1, the DOE Qualified Software List under IRS 179D energy tax credit regulations for commercial buildings (Energy.Gov 2015), the RESNET Home Energy Rating System software approval process (RESNET 2015), the *International Energy Conservation Code* (IECC 2015), the *International Green Construction Code*® (IgCC 2015), and ASHRAE *Standard* 189.1.

8.1 METHODOLOGICAL BASIS

There are three ways to evaluate a whole-building energy simulation program's accuracy (Judkoff et al. 1983/2008; Judkoff and Neymark 2006, 2009):

- *Empirical validation*, which compares calculated results from a program, subroutine, algorithm, module, or software object to monitored data from a real building, test cell, or laboratory experiment
- *Analytical verification*, which compares the output from a program, subroutine, algorithm, module, or software object to results from a known analytical solution or to results from a set of closely agreeing quasi-analytical solutions or verified numerical models
- *Comparative testing*, which compares a program to itself or to other programs

Neymark and Judkoff (2002) summarize approximately 100 articles and research papers on analytical, empirical, and comparative testing, from 1980 through 2015. Some of these and other works are listed by subject in the Bibliography.

Table 8 compares these techniques (Judkoff 1988; Judkoff and Neymark 2006, 2009; Judkoff et al. 1983/2008). In this table, the term "model" is the representation of reality for a given physical behavior. For example, heat transfer may be simulated with one-, two-, or three-dimensional thermal conduction models. The term "solution process" encompasses the mathematics and computer coding to solve a given model. The solution process for a model can be perfect, while the model remains inappropriate for a given physical situation, such as using a one-dimensional conduction model where two-dimensional conduction dominates. The term "truth standard" represents the standard of accuracy for predicting real behavior. An analytical solution is a "mathematical truth standard," and only tests the solution process for a model, not the appropriateness of the model. An approximate truth standard from an experiment tests both the solution process and appropriateness of the model within experimental uncertainty. The ultimate (or "absolute") validation truth standard would be comparison of simulation results to a perfectly performed empirical validation experiment, with all simulation inputs perfectly defined.

Empirical Validation

Establishing an absolute truth standard for evaluating a program's ability to analyze physical behavior requires empirical validation, but this is only possible within the range of measurement uncertainty, including that related to instruments, spatial and temporal discretization, and the overall experimental design. Full-scale test cells and buildings are large, relatively complex experimental objects. The exact design details, material properties, and construction in the field cannot be perfectly known, so there is uncertainty about the simulation model inputs that accurately represent the experimental object. Meticulous care is required to describe the experimental apparatus as clearly as possible to modelers to minimize this uncertainty. This includes experimental determination of as many material properties and other simulation model inputs as possible, including overall building parameters such as overall steady-state heat transmission coefficient (UA_o), infiltration (in the form of an effective UA), and thermal capacitance (Judkoff et al. 2000; Neymark et al. 2005; Subbarao 1988). Measuring these overall parameters allows for a closure check on the individual parameters that comprise the overall parameters (e.g., building envelope material properties or individual steady-state envelope component conductances that sum up to the measured overall steady-state heat transmission coefficient). Also required are detailed on-site meteorological measurements. For example, many experiments measure global horizontal solar radiation, but very few experiments measure the splits between direct, diffuse, and ground-reflected radiation, all of which are inputs to many whole-building energy simulation

programs. Small-scale test cells also have shortcomings because of similitude factors for air convection and the increased relative proportion of corner conditions, which increases the importance of 2D and 3D heat transfer. Side-by-side experimental design can help to dampen the effects of input uncertainties, if the effects of the intentional differences between test objects are robust compared to those of the unintentional differences.

The National Renewable Energy Laboratory (NREL) divides empirical validation into different levels, because many past validation studies produced inconclusive results. The levels of validation depend on the degree of control over possible sources of error in a simulation. The higher the degree of control over error sources, the better the potential for diagnosing the causes of measured to modeled output differences. The error sources consist of seven types, divided into two groups (Judkoff et al. 1983/2008):

External Error Types

- Differences between actual building microclimate versus weather input used by the program
- Differences between actual schedules, control strategies, effects of occupant behavior, and other effects from the real building versus those assumed by the program user
- User error deriving building input files
- Differences between actual physical properties of the building (including HVAC systems) versus those input by the user

Internal Error Types

- Differences between actual thermal transfer mechanisms in the real building and its HVAC systems versus the simplified model of those processes in the simulation (all models, no matter how detailed, are simplifications of reality)
- Errors or inaccuracies in the mathematical solution of the models
- Coding errors
- Ambiguous, incomplete, or faulty documentation

The simplest level of empirical validation compares a building's actual long-term energy use to that calculated by a computer program, with no attempt to eliminate sources of discrepancy. Because this is similar to how a simulation tool is used in practice, it is favored by many in the building industry. However, it is difficult to interpret the results because all possible error sources are acting simultaneously. Even if there is good agreement between measured and calculated performance, possible offsetting errors prevent a definitive conclusion about the model's accuracy. More informative levels of validation involve controlling or eliminating various combinations of error types and increasing the information density of output-to-data comparisons (e.g., comparing temperature and energy results at time scales ranging from subhourly to annual). At the most detailed level, all known sources of error are controlled to identify and quantify unknown error sources and to reveal causal relationships associated with error sources, thereby facilitating diagnostics. Long-term (ideally annual) overall energy use needed to maintain comfort has extra meaning as a metric, because it is an indicator of how important a fault or simplification in a simulation program is in the context of one of the model's most important uses. A $15/yr error out of a $1500/yr energy bill is tolerable, but a $500/yr error is not. Other measurements, such as fluxes through individual surfaces, or short-term temperatures, are important to establish cause and effect but are inherently less indicative by themselves of the overall importance of an error. For example, it is difficult to assess the importance of a 0.3 K absolute average hourly one-week error between simulated and measured zone temperature.

These principles also apply to intermodel comparative testing and analytical verification. The more realistic the test case, the more difficult it is to establish causality and diagnose problems; the simpler and more controlled the test case, the easier it is to pinpoint sources of error or inaccuracy. Methodically building up from simple, highly controlled cases to realistic cases one parameter at a time is useful for understanding the impact of assumptions and simplifications in building energy simulation programs.

Analytical Verification

Analytical verification compares outputs from a program, subroutine, algorithm, or software object to results from a known analytical solution or to results from a set of closely agreeing quasi-analytical solutions or verified numerical models. Here, the term **analytical solution** is the closed-form mathematical solution of a model that has an exact result for a given set of parameters and simplifying assumptions. The term **quasi-analytical solution** is the mathematical solution of a model for a given set of parameters and simplifying assumptions, which may require minor interpretation differences that cause minor results variations. Such a result may be computed by generally accepted numerical methods or other means, provided that such calculations occur outside the environment of a whole-building energy simulation program and can be scrutinized. The term **verified numerical model** is a numerical model with solution accuracy verified by close agreement with an analytical solution and/or other quasi-analytical or numerical solutions, according to a process that demonstrates convergence in the space and time domains. Such numerical models may be verified by applying an initial comparison with an analytical solution(s), followed by comparisons with other numerical models for incrementally more realistic cases where analytical solutions are not available.

Mathematical Truth Standards. An analytical solution provides an exact **mathematical truth standard**, limited to highly constrained cases for which exact analytical solutions can be derived. A **secondary mathematical truth standard** can be established based on the range of disagreement of a set of closely agreeing verified numerical models or other quasi-analytical solutions. Once verified against all available classical analytical solutions, and compared with each other for a number of other diagnostic test cases that do not have exact analytical solutions, the secondary mathematical truth standard can be used to test other models as implemented within whole-building simulation programs. Although a closed-form analytical solution provides the best possible mathematical truth standard, a secondary mathematical truth standard greatly enhances diagnostic capability for identifying software bugs and modeling errors as compared to the purely comparative method. This is because the range of disagreement among the results that comprise the secondary truth standard is typically much narrower than the range of disagreement among whole-building simulations. The secondary mathematical truth standard also allows more realistic (less constrained) boundary conditions to be used in the test cases, extending the analytical verification method beyond the constraints inherent for classical analytical solutions. This extends the usefulness of analytical verification methods by applying comparative techniques methodically, as outlined below.

Establishing Secondary Mathematical Truth Standards. The following methodology for verifying numerical models to develop a secondary mathematical truth standard facilitates extension of analytical verification techniques. The methodology applies to both development of test cases and implementation of the numerical models. The logic may be summarized as follows:

- Identify or develop exact analytical solutions that may be used as mathematical truth standards for testing detailed numerical models using parameters and simplifying assumptions of the analytical solution.
- Apply a numerical solution process that demonstrates convergence in the space and time domains for both the analytical-solution test cases and additional test cases where numerical models are applied.

Licensed for single user. © 2021, ASHRAE, Inc.

- Once validated against the analytical solutions, use the numerical models to develop test cases that progress toward more realistic (less idealized) conditions but do not have exact analytical solutions.
- Check the numerical models by rigorously comparing their results to each other while developing the more realistic cases.
- Tight agreement for the numerical models versus the analytical solution (and versus each other for subsequent test cases) verifies them as a secondary mathematical truth standard based on the range of disagreement among them.
- Use the verified numerical-model results as reference results for testing other models of the given behavior, which reside within whole building energy simulation computer programs.

Example applications of establishing secondary mathematical truth standards are provided in Neymark et al. (2008, 2009).

Other Considerations. The following general guidelines are helpful when developing effective empirical validation, analytical verification, and comparative test cases:

- Make test cases as simple as possible, to minimize input errors.
- Make test cases as robust as possible, to maximize signal to noise ratio for a tested feature.
- Vary test cases incrementally (varying just a single parameter when possible) so disagreements among results can be quickly diagnosed.
- For numerical models, check sensitivity to spatial and temporal discretization, length of simulation, convergence tolerance, iteration limits, etc., and demonstrate that modeling is at a level of detail where including further detail yields negligible sensitivity in the results; document such work in detailed modeler reports.
- Use independently developed and implemented models, and revise the test specification as needed to accommodate various modeling approaches; this reduces bias by ensuring that the test specification clearly addresses different modeling approaches.
- For resolving disagreements among results that comprise a secondary truth standard, it is helpful to use an additional, independent expert party not directly involved in developing the models or results being compared.
- Corrections to models must have a clear mathematical or physical basis and must be consistently applied across all test cases. Arbitrary alteration of a model solely for the purpose of better matching a given data set is not allowed.
- A greater number of results from independently developed quasi-analytical solutions or verified numerical solution models may be helpful for diagnosing disagreements among them.

Combining Empirical, Analytical, and Comparative Techniques

A comparison between measured and calculated performance represents a small region in an immense *N*-dimensional parameter space. Investigators are constrained to exploring relatively few regions in this space, yet would like to ensure that the results are not coincidental (e.g., not a result of offsetting errors) and represent the validity of the simulation elsewhere in the parameter space. Analytical and comparative techniques minimize the uncertainty of extrapolations around the limited number of sampled empirical domains. Table 9 classifies these extrapolations.

Figure 19 shows one process to combine analytical, empirical, and comparative techniques. These three techniques may also be used together in other ways; for example, intermodel comparisons may be done before an empirical validation exercise, to better define the experiment and to help estimate experimental uncertainty by propagating all known error sources through one or more whole-building energy simulation programs (Hunn et al. 1982; Lomas et al. 1994).

Table 9 Types of Extrapolation

Obtainable Data Points	Extrapolation
A few climates	Many climates
Short-term total energy use	Long-term total energy use, or vice versa
Short-term (hourly) temperatures and/or fluxes	Long-term total energy use, or vice versa
A few equipment performance points	Many equipment performance points
A few buildings representing a few sets of variable and parameter combinations	Many buildings representing many sets of variable and parameter combinations, or vice versa*
Small-scale: simple test cells, buildings, and mechanical systems; laboratory experiments	Large-scale complex buildings with complex HVAC systems, or vice versa

Source: Judkoff and Neymark (2006).
*Extrapolation can go both ways (e.g., from short- to long-term data and from long- to short-term data). This does not mean that such extrapolations are correct, only that researchers and practitioners have explicitly or implicitly made such inferences in the past.

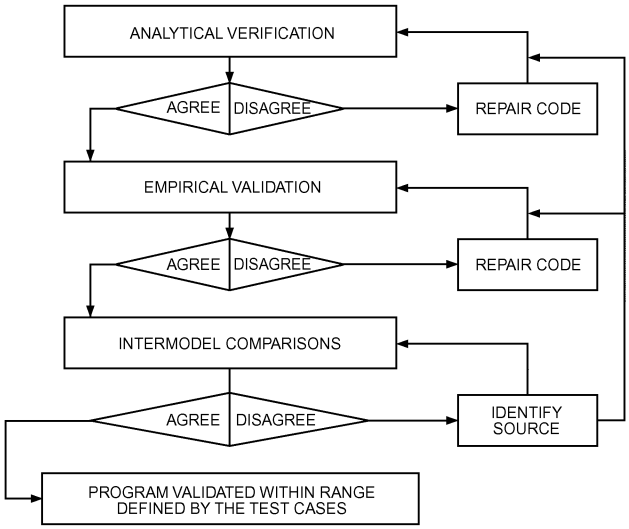

Fig. 19 Validation Method
(Judkoff et al. 1983/2008)

For the path shown in Figure 19, the first step is running the code against analytical verification test cases to check its mathematical solutions. Discrepancies must be corrected before proceeding further. Second, the code is run against high-quality empirical validation data, and errors are corrected. Diagnosing error sources can be quite difficult. Comparative techniques can be used to create diagnostic procedures (Achermann and Zweifel 2003; Judkoff 1988; Judkoff and Neymark 1995a, 1995b; Judkoff et al. 1980, 1983/2008; Morck 1986; Neymark and Judkoff 2002, 2004; Purdy and Beausoleil-Morrison 2003; Spitler et al. 2001; Yuill and Haberl 2002) and better define the empirical experiments. The third step is to check agreement of several different programs with different thermal solution and modeling approaches (that have passed through steps 1 and 2) in a variety of representative cases. This uses the comparative technique as an extrapolation tool. Deviations in the program predictions indicate areas for further investigation.

When programs successfully complete these three stages, they are considered validated for cases where acceptable agreement was achieved (i.e., for the range of building, climate, and mechanical system types represented by the test cases). Once several detailed simulation programs have satisfactorily completed the procedure, other programs and simplified design tools can be tested against them. A validated code does not necessarily represent truth. It does represent

Licensed for single user. © 2021, ASHRAE, Inc.

a set of algorithms that have been shown, through a repeatable procedure, to perform according to the current state of the art. Similarly, the example results and associated computer programs in the nonnormative sections of *Standard* 140 do not represent truth, but rather an attempt to identify the range of uncertainty in the current state of the art via a well-defined and repeatable procedure. It is anticipated that, as building energy simulation programs improve, the informative example results in *Standard* 140 will be periodically updated, and the range of differences among test case results may be reduced.

The NREL methodology for validating building energy simulation programs has been generally accepted by the International Energy Agency (Irving 1988), ASHRAE *Standard* 140, ASHRAE *Standard* 90.1, and elsewhere, with refinements suggested by other researchers (Bland 1992; Bloomfield 1988, 1999; Guyon and Palomo 1999b; Irving 1988; Lomas 1991; Lomas and Bowman 1987; Lomas and Eppel 1992). Additionally, the Commission of European Communities has conducted considerable work under the PASSYS program (Jensen 1989; Jensen and van de Perre 1991).

Testing Model Calibration Techniques Using Synthetic Data

Calibration is commonly used in conjunction with energy retrofit audit models (Judkoff et al. 2011a, 2011b; Reddy et al. 2006). This test method was initially developed by NREL for testing calibration procedures used with residential retrofit audit software; however, the fundamental concept could also be applied in a commercial building context. Other terms frequently used to describe model calibration include model tuning, model true-up, and model reconciliation.

Typically, residential and commercial model calibration has been implemented using monthly energy data collected from utility bills for an existing building that is about to receive an energy retrofit. Sometimes submetered, disaggregated, or higher-frequency data are also available. An audit gathers information about the building needed to construct an input file for a building energy simulation program. A calibration method reconciles model predictions with the data, and then the calibrated model is used to predict energy savings and energy cost savings from various combinations of retrofit measures. Many variations on this approach exist, including some where the savings predictions are subjected to calibration instead of, or along with, the model inputs.

Although it is logical to use the building's actual performance data to tune the model, it is not certain that this results in a model that better predicts post-retrofit energy savings. When calibrating a large number of inputs to a limited number of outputs (in mathematics, an underdetermined or overparameterized problem), there are many combinations of input parameters that result in a close match to the utility bill data, so a close match is not in itself proof of good calibration (Reddy et al. 2006). The lower the frequency or informational content of the building performance data, the lower the probability that the calibration actually improves the model and associated energy savings predictions. Therefore, any method to test calibration techniques should use as many of the following three figures of merit as possible: (1) accuracy of the savings prediction, (2) how closely the calibrated input parameter values match the actual parameter values, and (3) the goodness of fit between the modeled and measured data. A limiting factor in attempting to empirically validate calibration techniques is the lack of high-quality annual monthly pre- and post-retrofit energy data, (higher frequency and submetered data are better), good pre- and post-retrofit building characteristics data, local pre- and post-retrofit weather data, and the dates of the retrofit installations. Until enough such empirical data are available to researchers, an alternative analytical method can be used in which a simulation program is used to generate its own synthetic pre and post-retrofit energy performance data. The synthetic data may be used as a surrogate for actual data. The method follows these general procedures:

1. Specify a building for a test case and introduce input uncertainty into the test specification (this represents the uncertainty associated with developing inputs from audit survey data):
   (a) Perform sensitivity tests on inputs with potentially high uncertainties to determine their relative effects on outputs; select inputs that have both substantial uncertainties and effects on outputs as **approximate inputs**.
   (b) Specify an uncertainty range (**approximate input range**) for each approximate input.
   (c) Select **explicit inputs** from the approximate input ranges (those who perform the calibrations must not know the explicit inputs).
2. Perform simulations using explicit inputs to create synthetic utility bill data. (Currently, this is typically monthly data, but the method can be used to generate and test against higher- or lower-frequency synthetic building energy performance data, or end-use data at varying levels of disaggregation, mimicking the availability of submetered data).
   (a) Perform simulations to generate post-retrofit energy savings results by adjusting appropriate base-case inputs, including explicit inputs, as specified for each retrofit case and combinations of cases.
3. Develop tested program results (those who do this must not know the explicit inputs):
   (a) Develop the preliminary base-case model for a given calibration scenario.
   (b) Predict energy savings using one of the following:
      i. Calibrate the base-case model inputs using synthetic utility bills (from step 2), then apply the specified retrofit cases to the calibrated model.
      ii. Apply the specified retrofit to the uncirculated base case model and then calibrate or correct energy savings predictions using the synthetic utility bills (without adjustment to base-case model inputs); for example, (Calibrated savings) = (Predicted savings) × (Base-case actual bills)/(Base-case predicted bills).
      iii. Other calibration methods. The test cases make no recommendation about how to perform calibrations. Any calibration method that seeks to improve energy savings predictions through use of pre-retrofit building energy performance data can be tested by this method.
4. Use the following comparisons as figures of merit to determine the usefulness of the calibration techniques being tested. Note that all three of the listed comparisons are important for assessing the accuracy of the calibration technique. A large disagreement in any one of them indicates the presence of compensating errors, or some other error.
   (a) Compare the savings predictions from the tested program and any associated calibration techniques, versus the savings predictions from the same program run with the explicit inputs.
   (b) Compare the goodness of fit between synthetic building energy performance data and the calibrated model output data for the pre-retrofit case(s).
   (c) For programs where a calibrated base-case model is applied (see step 3bi), compare tested program inputs resulting from the tested program's calibration techniques to the randomly selected explicit inputs.

The preceding method is a pure (isolated) test of the calibration technique: that is, the synthetic utility billing data are generated with the tested program, and the program accuracy related to building physics modeling is not tested. A pure calibration test requires (1) automated calibration where no human judgment is required that would be helped by knowing the explicit inputs, or (2) that the modeler running the calibration test does not know the

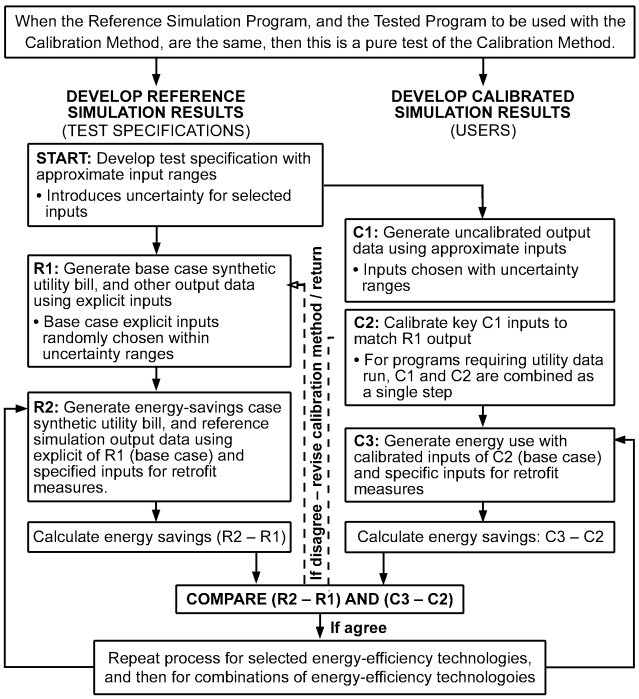

Fig. 20 Calibration Cases Conceptual Flow
(Judkoff et al. 2011a)

explicit inputs used to develop the synthetic utility bills. This method facilitates self-testing of a calibration technique, and is useful in several ways, including (1) testing a single calibration method, (2) testing several calibration methods to determine under what test conditions each is best, and (3) investigating how much and what kind of informational content is needed in the synthetic calibration data to achieve good calibrations with different calibration methods. The pure calibration test, however, may not be practical for a certification test that must be administered by a third-party organization; for this case, a method developed by NREL (Judkoff et al. 2011a, 2011b) ensures that the person performing the test does not know the explicit inputs. The main feature of this test method is that several (preferably at least three) reference programs are used to generate the synthetic utility bills and create the reference energy savings data. The bills and savings are taken as the average of the reference program results. This method tests both the calibration technique, and how closely the physics models in the tested program match the physics models in the reference programs. Example acceptance criteria may be used to facilitate the comparison of energy savings predictions (Judkoff et al. 2011a). Figure 20 shows the overall conceptual approach to testing model calibration techniques.

CHAPTER 20

SPACE AIR DIFFUSION

Indoor Air Quality and Sustainability 20.2
Terminology 20.2
Principles of Jet Behavior 20.3
Symbols 20.8

ROOM air distribution systems are intended to provide thermal comfort and ventilation for space occupants and processes. Although air terminals (inlets and outlets), terminal units, fan-coil units, local ducts, and rooms themselves may affect room air diffusion, this chapter addresses only air inlets and outlets and their direct effect on occupant comfort. This chapter is intended to present HVAC designers the fundamental characteristics of air distribution devices. For information on naturally ventilated spaces, see Chapter 16. For a discussion of various air distribution strategies, tools, and guidelines for design and application, see Chapter 57 in the 2019 *ASHRAE Handbook—HVAC Applications*. Chapter 20 in the 2020 *ASHRAE Handbook—HVAC Systems and Equipment* describes the characteristics of various air inlets, outlets, fan-coil units, chilled beams, air curtain units, and terminal units, as well as selection tools and guidelines.

Room air diffusion methods can be classified as one of the following as shown in Figure 1:

- **Mixed systems** produce little or no thermal stratification of air within the space. Overhead air distribution is an example of this type of system.
- **Fully (thermally) stratified systems** produce little or no mixing of air within the occupied space. Thermal displacement ventilation is an example of this type of system.
- **Partially mixed systems** provide some mixing within the occupied and/or process space while creating stratified conditions in the volume above. Most underfloor air distribution and task/ambient conditioning designs are examples of this type of system.

The preparation of this chapter is assigned to TC 5.3, Room Air Distribution.

Local temperature and carbon dioxide (CO_2) concentration have similar stratification profiles.

Air distribution systems, such as thermal displacement ventilation (TDV) and underfloor air distribution (UFAD), that deliver air in cooling mode at or near floor level and return air at or near ceiling level produce varying amounts of room air stratification. For floor-level supply, thermal plumes that develop over heat sources in the room play a major role in driving overall floor-to-ceiling air motion. The amount of stratification in the room is primarily determined by the balance between total room airflow and heat load. In practice, the actual temperature and concentration profile depends on the combined effects of various factors, but is largely driven by the characteristics of the room supply airflow and heat load configuration.

For room supply airflow, the major factors are

- Total room supply airflow quantity
- Room supply air temperature
- Diffuser type
- Diffuser throw height (or outlet velocity); this is associated with the amount of mixing provided by a floor diffuser (or room conditions near a low-sidewall TDV diffuser)

For room heat loads, the major factors are

- Magnitude and number of loads in space
- Load type (point or distributed source)
- Elevation of load (e.g., overhead lighting, person standing on floor, floor-to-ceiling glazing)
- Radiative/convective split
- Whether pollutants are associated with heat sources

1. INDOOR AIR QUALITY AND SUSTAINABILITY

Air diffusion methods affect not only indoor air quality (IAQ) and thermal comfort, but also energy consumption over the building's life. Choices made early in the design process are important. Programs such as U.S. Green Building Council's (USGBC 2013) Leadership in Energy and Environmental Design (LEED®) v4 rating system, which was originally created in response to indoor air quality concerns, now include prerequisites and credits for increasing ventilation rates and improving indoor environmental quality. These program requirements are sometimes achievable by following good room air diffusion design principles, methods, and standards (see Chapter 57 of the 2019 *ASHRAE Handbook—HVAC Applications*).

ANSI/ASHRAE *Standard* 62.1 provides a table of typical values to help predict zone air distribution effectiveness. For example, well-designed ceiling-based air distribution systems produce near-perfect air mixing in cooling mode, and yield an air distribution effectiveness of 1.0. Displacement ventilation and underfloor air distribution (UFAD) systems have the potential for values greater than 1.0. More information on ceiling- and wall-mounted air inlets and outlets can be found in Rock and Zhu (2002). Displacement system performance is described in Chen and Glicksman (2003). ASHRAE's (2013) *UFAD Design Guide* discusses UFAD in detail. More information on ANSI/ASHRAE *Standard* 62.1 is available in its user's manual (ASHRAE 2010).

2. TERMINOLOGY

Aspect ratio. Ratio of length to width of opening or core of a grille.

Attached jet. A supply air jet drawn to a surface, parallel to the direction of airflow and caused by the Coanda effect.

Axial jet. A supply air jet with a conical discharge profile.

Centerline velocity. Maximum velocity of an air jet at any given cross section perpendicular to the direction of airflow.

Coanda effect. Effect of a moving jet attaching to a parallel surface because of negative pressure developed between jet and surface.

Coefficient of discharge. Ratio of area at vena contracta to free area of opening.

Core area. Area of a register, grille, or linear slot diffuser pertaining to the inside of the frame or border.

Diffusion. Distribution of air into a space.

Distribution. Moving air to or in a space by an outlet discharging supply air.

Draft. Current of air, when referring to localized effect (generally, the unwanted local cooling of the body caused by air movement) caused by one or more factors of high air velocity, low ambient temperature, or direction of airflow whereby more heat is withdrawn from a person's skin than is normally dissipated.

Drop. Vertical distance that the lower edge of a horizontally projected airstream descends between the outlet and the end of its throw.

Effective area. Net area of an outlet or inlet device through which air can pass; equal to the free area times the coefficient of discharge.

Entrainment. Air drawn into an air jet because of the pressure differential caused by the airstream discharged from the outlet.

Entrainment ratio. Volumetric flow rate of total air (supply air plus entrained air) at a given distance from an outlet divided by the volumetric flow rate of supply air.

Free area. Total minimum area of openings in an air outlet or inlet through which air can pass.

Free jet. An air jet not obstructed or affected by walls, ceiling, or other surfaces.

Induction. Movement of space air into an air device.

Induction ratio. Volumetric flow rate of induced air divided by volumetric flow rate of primary air.

Inlet. A device that allows air to exit the zone (e.g., grilles, registers, diffusers)

Isothermal jet. An air jet in which supply air temperature equals surrounding room air temperature.

Linear jet. A supply air jet with a relatively high aspect ratio.

Neck area. Nominal area of duct connection to air outlet or inlet.

Nonisothermal jet. An air jet in which supply air temperature does not equal surrounding room air temperature.

Occupied zone. The volume of space intended to be comfort conditioned for occupants (see ANSI/ASHRAE *Standard* 55).

Outlet. A device discharging supply air into the space (e.g., grilles, registers, diffusers). Classified according to location and type of discharge.

Outlet velocity. Average velocity of air discharging from an outlet.

Primary air. Air delivered to an outlet or terminal device.

Radial jet. A supply air jet that discharges 360° and expands uniformly.

Spread. Divergence of an airstream in a horizontal and/or vertical plane after it leaves an outlet.

Stratification height. Vertical distance from floor to horizontal plane that defines lower boundary of upper mixed zone in a fully stratified or partially mixed system.

Stratified zone. Zone in which air movement is entirely driven by buoyancy caused by convective heat sources. Typically found in fully stratified or partially mixed systems.

Supply Air. Air delivered into a zone from an outlet.

Terminal velocity. An arbitrary specified centerline air velocity at a distance from an outlet.

Throw. The distance from the centerline of an outlet perpendicular to a point in the mixed airstream where the velocity has been reduced to a specified terminal velocity (e.g., 0.25, 0.5, 0.75, or 1.0 m/s), defined by ASHRAE *Standard* 70.

Total air. Combination of supply air and entrained air at a given distance from an outlet.

Vena contracta. Smallest cross-sectional area of a fluid stream leaving an orifice.

Outlet Types and Characteristics

Straub and Chen (1957) and Straub et al. (1956) classified outlets into five major groups (the subgrouping was added in 2017 and was not part of the original research):

Group A1. Outlets mounted in or near the ceiling that discharge air horizontally (Figures 2 and 3).

Group A2. Outlets discharging horizontally that are not influenced by an adjacent surface (free jet; Figure 4).

Group B. Outlets mounted in or near the floor that discharge air vertically in a linear jet (Figure 5).

Group C. Outlets mounted in or near the floor that discharge air vertically in a spreading jet (Figure 6).

Group D. Outlets mounted in or near the floor that discharge air horizontally (Figure 7 and 8). When used in fully stratified systems (TDV), these outlets use low discharge velocities; in mixed systems, they use higher discharge velocities.

Group E. Outlets that project supply air vertically downward (Figures 9 and 10). When used in partially stratified systems (e.g., laminar flow outlets, TDV), these outlets use low discharge velocities; in mixed systems (e.g., air curtain units, other downward directed ceiling devices, etc.), they use higher discharge velocities.

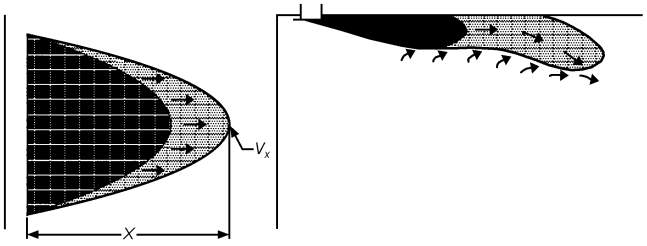

Fig. 3 Example Airflow Patterns (Nonisothermal) of Outlet Group A1

3. PRINCIPLES OF JET BEHAVIOR

Air Jet Fundamentals

Air supplied to rooms through various types of outlets can be distributed by turbulent air jets (mixed and partially mixed systems) or in a low-velocity, unidirectional manner (stratified systems). The air jet discharged from an outlet is a primary factor affecting room air motion. The jet boundary contours are not well defined and are easily affected by external influences. Baturin (1972), Christianson (1989), and Murakami (1992) have further information on the relationship between the air jet and occupied zone.

If the supply air temperature is equal to the ambient room air temperature, the air jet is called an **isothermal jet**. A jet with an initial temperature different from the ambient air temperature is called a **nonisothermal jet**. The air temperature differential between supplied and ambient room air generates thermal forces (buoyancy) in jets, affecting the jet's (1) trajectory, (2) location at which it attaches to and separates from the ceiling/floor, and (3) throw. The significance of these effects depends on the ratio between the thermal buoyancy of the air and jet momentum.

If an air jet is not obstructed or affected by walls, ceiling, or other surfaces, it is considered a **free jet**. When outlet area is small compared to the dimensions of the space normal to the jet, the jet may be considered free as long as

$$X \leq 1.5\sqrt{A_R} \tag{1}$$

where

X = distance from face of outlet, m

A_R = cross-sectional area of confined space normal to jet, m^2

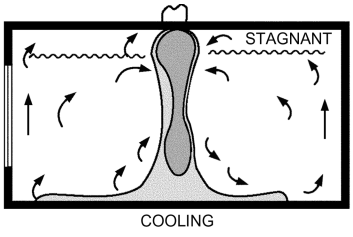

Fig. 9 Example Airflow Patterns (Nonisothermal) of Outlet Group E (High Velocity)

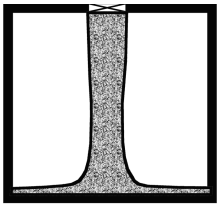

Fig. 10 Example Airflow Patterns (Nonisothermal) of Outlet Group E (Low Velocity)

Jet Expansion Zones. The full length of an air jet, in terms of the maximum or centerline velocity and temperature differential at the cross section, can be divided into four zones:

- Zone 1 extends from the outlet face, in which the velocity and temperature of the airstream remains practically unchanged.
- Zone 2 is a transition zone, with its length determined by the type of outlet, aspect ratio of the outlet, initial airflow turbulence, etc.
- Zone 3 is a zone of jet degradation, where centerline air velocity and temperature differential decrease rapidly. Turbulent flow is fully established and may be 25 to 100 equivalent air outlet diameters long. The angle of divergence is well defined. Typically, free air jets diverge at a constant angle, usually ranging from 20 to 24°, with an average of 22°. Coalescing jets for closely spaced multiple outlets expand at smaller angles, averaging 18°, and jets discharging into relatively small spaces show even smaller angles of expansion (McElroy 1943). The angle of divergence is easily affected by external influences, such as local eddies, vortices, and surges. Internal forces governing this air motion are extremely delicate (Nottage et al. 1952a).
- Zone 4 is important because, in most cases, the jet enters the occupied area in this zone. Distance to this zone and its length depend on the velocities and turbulence characteristics of ambient air. In a few diameters or widths, air velocity becomes less than 0.25 m/s.

Centerline Velocities in Zones 1 and 2. In zone 1, the ratio V_x/V_o is constant for a given outlet and ranges between 1.0 and 1.2, equal to the ratio of the centerline velocity of the jet at the start of expansion to the average initial velocity. The ratio V_x/V_o varies from approximately 1.0 for rounded entrance nozzles to about 1.2 for straight pipe discharges; it has higher values for diverging discharge outlets.

The aspect ratio (Tuve 1953) and turbulence (Nottage et al. 1952a) primarily affect centerline velocities in zones 1 and 2. Aspect ratio has little effect on the terminal zone of the jet when H_o is greater than 100 mm. This is particularly true of nonisothermal jets. When H_o is very small, induced air can penetrate the core of the jet, thus reducing centerline velocities. The difference in performance between a radial outlet with small H_o and an axial outlet with large H_o shows the importance of jet thickness.

When air is discharged from relatively large perforated panels, the constant-velocity core formed by coalescence of individual jets extends a considerable distance from the panel face. In zone 1, when the aspect ratio is less than 5, use the following equation for estimating centerline velocities (Koestel et al. 1949):

$$V_x = 1.2V_o\sqrt{C_d R_{fa}} \tag{2}$$

In zone 2, the ratio V_x/V_o begins to decrease. Experimental evidence indicates that, in zone 2,

$$\frac{V_x}{V_o} = \sqrt{\frac{K_{c2}H_o}{X}} \tag{3}$$

where

V_x = centerline velocity at distance X from outlet, m/s
V_o = $V_c/C_d R_{fa}$ = average initial velocity at discharge, m/s
V_c = nominal velocity of discharge based on core area, m/s
C_d = coefficient of discharge (usually between 0.65 and 0.90)
R_{fa} = ratio of free area to core area
H_o = width of jet at outlet or at vena contracta, m
K_{c2} = centerline velocity constant, depending on outlet type and discharge pattern
$X \geq (1/K_{c2}H_o)^{1/2}$ = distance from outlet to measurement of centerline velocity V_x, m

Centerline Velocity in Zone 3. In zone 3, centerline velocities of radial and axial isothermal jets can be determined accurately from the following equation:

Licensed for single user. © 2021 ASHRAE, Inc.

Table 1 Generic Values for Centerline Velocity Constant K_{c3}[a] for Commercial Supply Outlets for Fully and Partially Mixed Systems, Except UFAD

Outlet Type	Discharge Pattern	A_o	K_{c3}[a]
High sidewall grilles (Figure 4)	0° deflection[b]	Free	5.7
	Wide deflection	Free	4.2
High sidewall linear	Core less than 100 mm high[c]	Free	4.4
	Core more than 100 mm high	Free	5.0
Low sidewall (Figure 7)	Up and on wall, no spread	Free	4.5
	Wide spread[c]	Free	3.0
Baseboard	Up and on wall, no spread	Core	4.0
	Wide spread	Core	2.0
Floor grille (Figure 5)	No spread[c]	Free	4.7
	Wide spread	Free	1.6
Ceiling (Figure 2)	360° horizontal[d]	Neck	1.1
	Four-way; little spread	Neck	3.8
Ceiling linear slot (Figure 3)	Horizontal/vertical along surface[c]	Free	5.5
	Horizontal/vertical free jet[c]	Free	3.9
	Free jet (air curtain units)	Free	6.0

[a]Generic values shown for example purposes only. See manufacturer's data for specific K_{c3} values. [b]Free area is about 80% of core area. [c]Free area is about 50% of core area. [d]Cone free area is greater than duct area.

$$V_x = \frac{K_{c3} V_o \sqrt{A_o}}{X} = \frac{K_{c3} Q_o}{X\sqrt{A_o}} \quad (4)$$

where

K_{c3} = centerline velocity constant (see Table 1 for generic values)
$V_o = V_c/C_d R_{fa}$ = average initial velocity at discharge, m/s
A_o = free area, core area, or neck area as shown in Table 1 (obtained from outlet manufacturer), m^2
Q_o = volumetric flow rate of supply air, m^3/s
X = distance from face of outlet, m

For centerline velocities of linear jets, where $K_{c3} = K_{c2}$, use Equation (3).

The effective area, according to ASHRAE *Standard* 70, can be used in place of A_o in Equation (4) with the appropriate value of K_{c3}.

Centerline Velocity in Zone 4. In zone 4, centerline velocities can be difficult to predict, based on the large dispersal pattern.

Determining Centerline Velocities. To correlate data from all four zones, plot centerline velocity ratios against distance from the outlet in Figures 11 and 12.

Airflow patterns of diffusers are related to the centerline velocity constants and throw distance. In general, diffusers with a circular airflow pattern (radial jet) have a shorter throw than those with a directional or cross-flow pattern (axial jet). During cooling, the circular pattern tends to curl back from the end of the throw toward the diffuser, reducing the drop and ensuring that the cool air remains near the ceiling.

In cross-flow airflow patterns, the airflow does not roll back to the diffuser at the end of the throw, but continues to move away from the diffuser at low velocities.

Throw. At a given supply airflow and centerline velocity, Equation (4) can be transposed into Equation (5) to determine the throw X of an outlet. The centerline velocity constant and appropriate outlet area A_o should be available from the outlet manufacturer.

According to Figures 11 and 12, 0.25 m/s terminal velocity can occur in zone 4. When this occurs, an accepted practice to approximate throw in zone 4 is to reduce the calculated throw in zone 3 by 30%.

$$X = \frac{K_{c3} Q_o}{V_x \sqrt{A_o}} \quad (5)$$

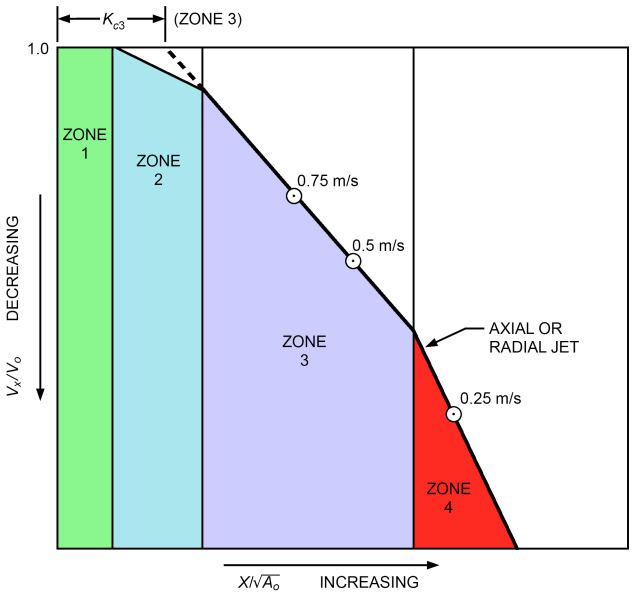

Fig. 11 Zones of Expansion for Axial or Radial Air Jets

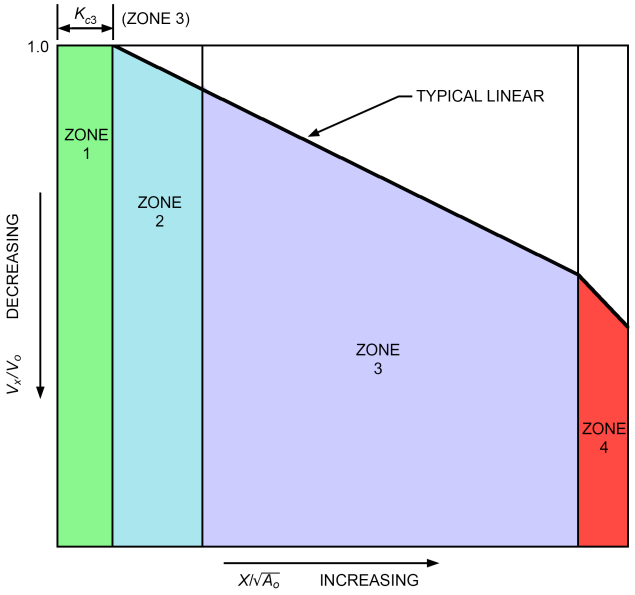

Fig. 12 Zones of Expansion for Linear Air Jets

See Informative Appendix B of ASHRAE *Standard* 70-2006 for the application of this methodology. The following example shows the use of Table 1 and Figures 11 and 12.

Example 1. A 300 by 450 mm high sidewall grille with an 280 by 430 mm core area is selected. From Table 1, $K_{c3} = 5$ for zone 3, and A_o should be 80% of the core area, in square metres. If the airflow is 0.3 m^3/s, what is the throw to 0.25, 0.5, and 0.75 m/s?

Solution:

From Equation (5),

$$X = \frac{K_{c3} Q_o}{V_x \sqrt{A_o}} = \frac{5.7 \times 0.3}{V_x \sqrt{0.8 \times 280 \times 430 / 10^6}} = \frac{1.71}{V_x \times 0.31}$$

Licensed for single user. © 2021 ASHRAE, Inc.

Solving for 0.25 m/s throw,

$$X = 1.71/(0.25 \times 0.31) = 22 \text{ m}$$

However, according to Figures 11 and 12, 0.25 m/s is in zone 4, which is typically 30% less than calculated in Equation (4), or

$$X = 22 \times 0.70 = 15 \text{ m}$$

Solving for 0.5 m/s throw,

$$X = 1.71/(0.5 \times 0.31) = 11 \text{ m}$$

Solving for 0.75 m/s throw,

$$X = 1.71/(0.75 \times 0.31) = 7 \text{ m}$$

Velocity Profiles of Jets. In zone 3 of both axial and radial jets, the velocity distribution may be expressed by a single curve (Figures 11 and 12) in terms of dimensionless coordinates; this same curve can be used as a good approximation for adjacent portions of zones 2 and 4. Temperature and density differences have little effect on cross-sectional velocity profiles.

Velocity distribution in zone 3 can be expressed by the Gauss error function or probability curve, which is approximated by the following equation:

$$\left(\frac{r}{r_{0.5V}}\right)^2 = 3.3 \log \frac{V_x}{V} \tag{6}$$

where

r = radial distance of point under consideration from centerline of jet
$r_{0.5V}$ = radial distance in same cross-sectional plane from axis to point where velocity is one-half centerline velocity (i.e., $V = 0.5V_x$)
V_x = centerline velocity in same cross-sectional plane
V = actual velocity at point being considered

Experiments show that the conical angle for $r_{0.5V}$ is approximately one-half the total angle of divergence of a jet. The velocity profile curve for one-half of a straight-flow turbulent jet (the other half being a symmetrical duplicate) is shown in Figure 13. For multiple-opening outlets, such as grilles or perforated panels, the velocity profiles are similar, but the angles of divergence are smaller.

Entrainment Ratios. The following equations are for entrainment of circular jets and of jets from long slots. For third-zone expansion of circular jets,

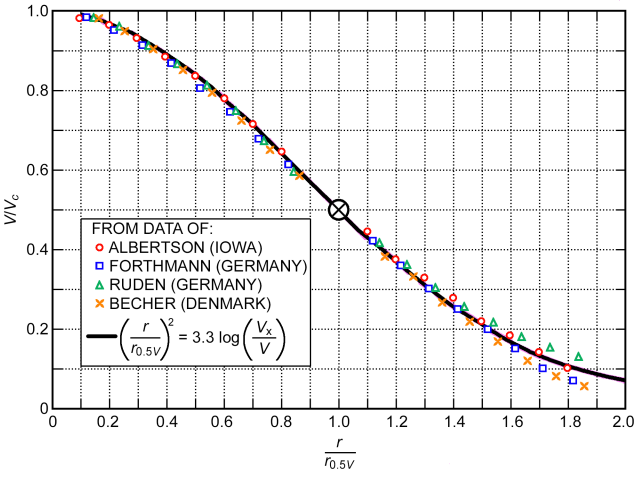

Fig. 13 Cross-Sectional Velocity Profiles for Straight-Flow Turbulent Jets

$$\frac{Q_x}{Q_o} = \frac{2X}{K_c\sqrt{A_o}} \tag{7}$$

By substituting from Equation (4),

$$\frac{Q_x}{Q_o} = 2\frac{V_o}{V_x} \tag{8}$$

For a continuous slot with active sections up to 3 m and separated by 0.6 m,

$$\frac{Q_x}{Q_o} = \sqrt{\frac{2}{K_{c3}}}\sqrt{\frac{X}{H_o}} \tag{9}$$

or, substituting from Equation (3),

$$\frac{Q_x}{Q_o} = \sqrt{2}\frac{V_o}{V_x} \tag{10}$$

where

Q_x = total volumetric flow rate at distance X from face of outlet, m^3/s
Q_o = discharge from outlet, m^3/s
X = distance from face of outlet, m
K_c = centerline velocity constant
A_o = core area or neck area free (see Table 1), m^2

The entrainment ratio Q_x/Q_o is important in determining total air movement at a given distance from an outlet. For a given outlet, the entrainment ratio is proportional to the distance X [Equation (7)] or to the square root of the distance X [Equation (9)] from the outlet. Equations (8) and (10) show that, for a fixed centerline velocity V_x, the entrainment ratio is proportional to outlet velocity. Equations (8) and (10) also show that, at a given centerline and outlet velocity, a circular jet has greater entrainment and total air movement than a long slot. Comparing Equations (7) and (9), the long slot should have a greater rate of entrainment. The entrainment ratio at a given distance is less with a large K_{c3} than with a small K_{c3}.

Isothermal Radial Flow Jets

In a radial jet, as with an axial jet, the cross-sectional area at any distance from the outlet varies as the square of this distance. Centerline velocity gradients and cross-sectional velocity profiles are similar to those of zone 3 of axial jets, and the angles of divergence are about the same.

Nonisothermal Jets

When the temperature of introduced air is different from the room air temperature, the diffuser air jet is affected by thermal buoyancy caused by air density difference. The trajectory of a nonisothermal jet introduced horizontally is determined by the Archimedes number (Baturin 1972):

$$\text{Ar} = \frac{gL_o(T_o - T_A)}{V_o^2 T_A} \tag{11}$$

where

g = gravitational acceleration rate, m/s^2
L_o = length scale of diffuser outlet equal to hydraulic diameter of outlet, m
$(T_o - T_A)$ = initial temperature of jet – temperature of ambient air, °C
V_o = initial air velocity of jet, m/s
T_A = room air temperature, K

The influence of buoyant forces on horizontally projected heated and chilled jets is significant in heating and cooling with wall outlets. Koestel's (1955) equation describes the behavior of these jets.

Helander and Jakowatz (1948), Helander et al. (1953, 1954, 1957), Knaak (1957), and Yen et al. (1956) developed equations for outlet characteristics that affect the downward throw of heated

Licensed for single user. © 2021 ASHRAE, Inc.

air. Koestel (1954, 1955) developed equations for temperatures and velocities in heated and chilled jets. Kirkpatrick and Elleson (1996) and Li et al. (1993) provide additional information on nonisothermal jets.

Nonisothermal Horizontal Free Jet

A horizontal free jet rises or falls according to the temperature difference between it and the ambient environment. The horizontal jet throw to a given distance follows an arc, rising for heated air and falling for cooled air. Therefore, whether the equivalent temperature difference is positive or negative, the distance from the diffuser to a given terminal velocity along the discharge jet remains essentially the same.

Comparison of Free Jet to Attached Jet

An attached jet entrains air along the exposed side of the jet, whereas a free jet can entrain air on all its surfaces. Because a free jet's entrainment rate is larger compared to that of an attached jet, a free jet's throw distance will be shorter. To calculate the throw distance X for a noncircular free jet from catalog data for an attached jet, the following estimate can be used.

$$X_{free} = X_{attached} \times 0.707 \quad (12)$$

Jets from ceiling diffusers initially tend to attach to the ceiling surface, because of the force exerted by the Coanda effect. However, air jets detach from the ceiling if the airstream's buoyancy forces are greater than the inertia of the moving airstream.

With separation, a cold jet may enter the occupied space, and can result in thermal discomfort. The thermal discomfort is caused by two factors: the cold draft caused by the separated jet in the occupied space, and areas of the room not reached by the separated jet. The separation distance parameter x_s is the distance from the diffuser at which a jet separates from the ceiling.

Separation distance correlates with outlet jet conditions (Kirkpatrick and Elleson 1996). Separation distance depends on the velocity constant K_c, outlet temperature, flow rate, and static pressure drop. For slot and round diffusers,

$$x_s = (48.04)C_s K_c^{1/2}(\Delta T/T)^{-1/2} Q_o^{1/4} \Delta P^{3/8} \quad (13)$$

where

x_s = jet separation distance, m
C_s = separation coefficient, 1.2
K_c = centerline velocity constant
ΔT = room-jet temperature difference, K
T = average absolute room temperature, K
Q_o = outlet flow rate, m^3/s
ΔP = diffuser static pressure drop, Pa

Attached jets travel at a higher velocity and entrain less air than a free jet. Values of centerline velocity constant K_c are approximately those for a free jet multiplied by $\sqrt{2}$.

When a jet is discharged parallel to but at some distance from a solid surface (wall, ceiling, or floor), its expansion in the direction of the surface is reduced, and entrained air must be obtained by recirculation from the jet instead of from ambient air (McElroy 1943; Nottage et al. 1952b; Zhang et al. 1990). The restriction to entrainment caused by the solid surface induces the **Coanda effect**, which makes the jet attach to a surface after it leaves the diffuser outlet. The jet then remains attached to the surface for some distance before separating again.

In nonisothermal cases, the jet's trajectory is determined by the balance between thermal buoyancy and the Coanda effect, which depends on jet momentum and distance between the jet exit and solid surface. The behavior of such nonisothermal surface jets has been studied by Kirkpatrick et al. (1991), Oakes (1987), Wilson et al. (1970), and Zhang et al. (1990), each addressing different factors. More systematic study of these jets in room ventilation flows is needed to provide reliable guidelines for designing air distribution systems.

Air Curtain Units

Non-recirculating air curtain units operate in zones 1 to 3 where velocity degradation is at a minimum. The air curtain unit is designed such that the jet strikes the floor, comparable, surface or another jet in zone 3 at a minimum of 2 m/s, to generate a stable split to resist minimal thermal and pressure differentials.

Recirculating air curtain units also operate in zones 1 to 3, where velocity degradation is at a minimum. The target distance is designed for the jet to be captured by the low-pressure return and maintain a minimum of 3 m/s velocity while in zone 3, to create a stable barrier to resist minimal thermal and pressure differentials.

Multiple Jets

Twin parallel air jets act independently until they interfere. The point of interference and its distance from outlets vary with the distance between outlets. From outlets to the point of interference, maximum velocity, as for a single jet, is on the centerline of each jet. After interference, velocity on a line midway between and parallel to the two jet centerlines increases until it equals jet centerline velocity. From this point, maximum velocity of the combined jet stream is on the midway line, and the profile seems to emanate from a single outlet of twice the area of one of the two outlets.

Air Movement in Occupied Zone

Zhang et al. (1990) found that, for a given heat load and room air supply rate, air velocity in the occupied zone increases when outlet discharge velocity increases. Therefore, the design supply air velocity should be high enough to maintain the jet traveling in the desired direction, to ensure adequate mixing before it reaches the occupied zone. Excessively high outlet air velocity produces high air velocities in the occupied zone and may result in thermal discomfort.

Air turbulence in a room is mainly produced at the diffuser jet region by interaction of supply air with room air and with solid surfaces in the vicinity. It is then transported to other parts of the room, including the occupied zone (Zhang et al. 1992). Air in the occupied zone usually contains very small amounts of turbulent kinetic energy compared to the jet region. Because turbulence may cause thermal discomfort (Fanger et al. 1988), air distribution systems should be designed to avoid air turbulence in the occupied zone (except in specialized applications such as task ambient or spot-conditioning systems).

Thermal Plumes. As a thermal plume rises because of natural convection above a heat source, it entrains surrounding air and therefore increases in size and volume, and decreases in velocity (Figure 14). The maximum height to which a plume rises depends primarily on the heat source's strength (relative to the air turbulence surrounding the heat source), and secondarily on stratification in the room (which decreases the rising plume's buoyancy). The stratified zone has little or no recirculation.

In fully stratified and partially mixed applications, cool supply air introduced at or near the floor gradually flows across the lower level of the space. In the case of fully stratified applications (e.g., TDV systems), this layer is typically 100 to 150 mm thick. In partially mixed systems, this layer typically ranges from 0.3 to 2.4 m thick, depending on the upward vertical projection of the outlets' supply air jets. It is drawn horizontally toward convective heat sources located within or close to it, where it is entrained upward by the associated heat plume. Partially mixed systems are characterized by relatively well-mixed conditions from the floor up to the height where their supply air jet velocities decay to 0.25 m/s or less. This area is referred to as the **lower mixed zone**. These plumes expand and rise until they encounter equally warm air in the upper

Licensed for single user. © 2021 ASHRAE, Inc.

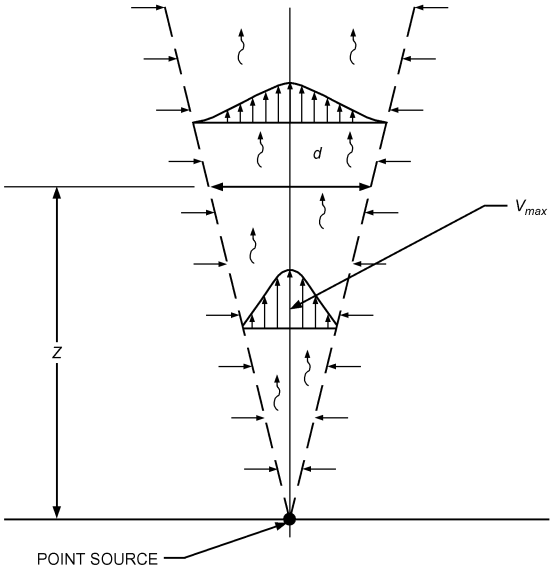

Fig. 14 Thermal Plume from Point Source

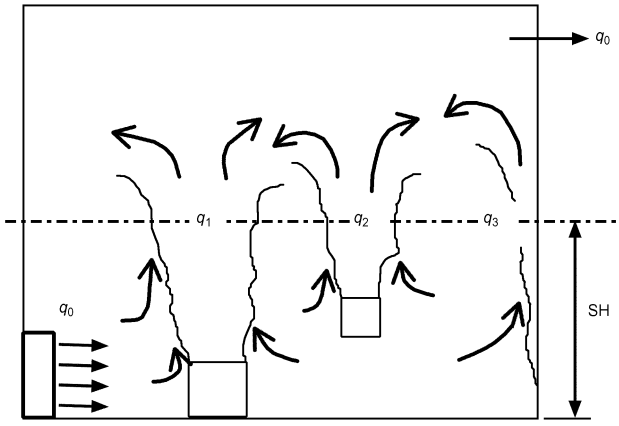

Fig. 15 Schematic Diagram of Major Flow Elements in Room with Displacement Ventilation

regions of the space. The **upper mixed zone** above the stratification height is characterized by low-velocity recirculation, which produces a fairly well-mixed layer of warm air with greater contaminant concentration than that in the lower levels of the space.

Typically, warmer, more polluted air will not reenter the stratified zone. This principle is the basis for the improved ventilation effectiveness and heat removal efficiency of TDV systems. In some situations (e.g., morning start-up, winter), there are also sources of cooling in the space, such as cold perimeter windows. The resulting cold downdraft may transport some air from the upper zone back down to the stratified zone.

Figure 15 shows basic elements in a simplified schematic of a TDV system. In the figure, q_0 represents the supply airflow into the room from a low sidewall diffuser, and q_1, q_2, and q_3 are the upward-moving airflows in thermal plumes that form above heat sources. In this simplified configuration, the stratification height occurs at a height SH, where the net upward-moving flow $q_1 + q_2 + q_3 = q_0$. An important objective in designing and operating a TDV system is to maintain stratification above the occupied zone.

4. SYMBOLS

A_c = measured gross (core) area of outlet, m^2
A_o = core area or neck area, m^2
A_R = cross-sectional area of confined space normal to jet, m^2
Ar = Archimedes number [Equation (11)]
c = pollutant concentration
C_d = discharge coefficient (usually between 0.65 and 0.90)
c_R = concentration of pollutant at return grille near ceiling level
g = gravitational acceleration rate, m/s^2
H = height or width of slot [Equation (2)], or of room
H_o = width of jet at outlet or at vena contracta or width of slot, m
K_{c2} = centerline velocity constant in zone 2
K_{c3} = centerline velocity constant in zone 3
L_o = length scale of diffuser outlet equal to hydraulic diameter of outlet, m
ΔP = diffuser static pressure drop, Pa
Q_o = discharge from outlet, m^3/s
Q_x = total volumetric flow rate at distance X from face of outlet, m^3/s
r = radial distance of point under consideration from centerline of jet
$r_{0.5V}$ = radial distance in same cross-sectional plane from axis to point where velocity is one-half centerline velocity (i.e., $V = 0.5V_x$)
R_{fa} = ratio of free area to gross (core) area
SH = stratification height
T = average absolute room temperature, K
ΔT = room/jet temperature difference, K
T_A = temperature of ambient air, °C
T_E = temperature at ceiling, °C
T_F = temperature near floor, °C
T_H = temperature at given height, °C
T_O = initial temperature of jet, °C
T_S = supply temperature, °C
V = actual velocity at point being considered
V_c = nominal velocity of discharge based on core area, m/s
V_o = initial air velocity of jet, m/s
V_T = terminal velocity, m/s
V_x = centerline velocity, m/s
X = distance from face of outlet to location of centerline velocity V_X, m
$X_{attached}$ = throw distance of attached jet, m
X_{free} = throw distance of free jet, m
X_H = throw height from floor outlet, m
X_{VT} = distance to given terminal velocity, m

COMMERCIAL, industrial, and residential air duct system design must consider (1) space availability, (2) noise levels, (3) air leakage, (4) balancing, (5) fire and smoke control, (6) initial investment cost, and (7) system operating cost.

Deficiencies in duct design can result in systems that operate incorrectly or are expensive (increased energy) to own and operate. Poor design or lack of system sealing can produce inadequate airflow rates at the terminals, leading to discomfort, loss of productivity, and even adverse health effects. Lack of sound attenuation may lead to objectionable noise levels. Proper duct insulation eliminates excessive heat gain or loss.

In this chapter, system design and calculation of a system's frictional and dynamic resistance (total pressure) to airflow are considered. Chapter 19 of the 2020 *ASHRAE Handbook—HVAC Systems and Equipment* examines duct construction and presents construction standards for residential, commercial, and industrial HVAC and exhaust systems. For design guidance specific to residential systems, refer to Manual D by ACCA (2014).

1. BERNOULLI EQUATION

The Bernoulli equation can be developed by equating the forces on an element of a stream tube in a frictionless fluid flow to the rate of momentum change. On integrating this relationship for steady flow, the following expression (Osborne 1966) results:

$$\frac{v^2}{2} + \int \frac{\Delta p}{\rho} + gz = \text{constant, N·m/kg} \quad (1)$$

where

v = streamline (local) velocity, m/s
p = absolute pressure, Pa (N/m^2)
ρ = density, kg/m^3
g = acceleration caused by gravity, m/s^2
z = elevation, m

Assuming constant fluid density in the system, Equation (1) reduces to

$$\frac{v^2}{2} + \frac{p}{\rho} + gz = \text{constant, N·m/kg} \quad (2)$$

Although Equation (2) was derived for steady, ideal frictionless flow along a stream tube, it can be extended to analyze flow through ducts in real systems with friction and dynamic losses. In terms of pressure, the relationship for fluid resistance between two sections is

$$\frac{\rho_1 V_1^2}{2} + p_1 + g\rho_1 z_1 = \frac{\rho_2 V_2^2}{2} + p_2 + g\rho_2 z_2 + \Delta p_{t,\,1\text{–}2} \quad (3)$$

where

V = average duct velocity, m/s
$\Delta p_{t,1\text{–}2}$ = total pressure loss caused by friction and dynamic losses between sections 1 and 2, Pa

In Equation (3), V (cross-section average velocity) replaces v (streamline velocity) because experimentally determined loss coefficients allow for errors in calculating $v^2/2$ (velocity pressure) across streamlines.

On the left side of Equation (3), add and subtract p_{z1}; on the right side, add and subtract p_{z2}, where p_{z1} and p_{z2} are the values of atmospheric air pressure at heights z_1 and z_2. Thus,

$$\frac{\rho_1 V_1^2}{2} + p_1 + (p_{z1} - p_{z1}) + g\rho_1 z_1 = \frac{\rho_2 V_2^2}{2} + p_2 + (p_{z2} - p_{z2}) + g\rho_2 z_2 + \Delta p_{t,1\text{-}2} \quad (4)$$

Atmospheric air pressure at any elevation (p_{z1} and p_{z2}) expressed in terms of the atmospheric pressure p_a at the same datum elevation is given by

$$p_{z1} = p_a - g\rho_a z_1 \quad (5)$$

$$p_{z2} = p_a - g\rho_a z_2 \quad (6)$$

Substituting Equations (5) and (6) into Equation (4) and simplifying yields the total pressure change between sections 1 and 2. Assume no temperature change between sections 1 and 2 (e.g., no heat exchanger or significant heat loss or gain within the section); therefore, $\rho_1 = \rho_2$. When a heat exchanger is located in the section, the arithmetic average of the heat exchanger inlet and outlet temperatures is generally used (with the heat exchanger treated as a duct section). Let $\rho = \rho_1 = \rho_2$, and $p_{s,1} = (p_1 - p_{z1})$ and $p_{s,2} = (p_2 - p_{z2})$ are gage pressures at elevations z_1 and z_2.

$$\Delta p_{t,1\text{–}2} = \left(p_{s,1} + \frac{\rho V_1^2}{2}\right) - \left(p_{s,2} + \frac{\rho V_2^2}{2}\right) + g(\rho_a - \rho)(z_2 - z_1) \quad (7a)$$

$$\Delta p_{t,1\text{–}2} = \Delta p_t + \Delta p_{se} \quad (7b)$$

Rearranging Equation (7b) yields

$$\Delta p_t = \Delta p_{t,1\text{-}2} - \Delta p_{se} \quad (7c)$$

where

$p_{s,1}$ = static pressure, gage at elevation z_1, Pa
$p_{s,2}$ = static pressure, gage at elevation z_2, Pa
V_1 = average velocity at section 1, m/s
V_2 = average velocity at section 2, m/s
ρ_a = density of ambient air, kg/m^3

The preparation of this chapter is assigned to TC 5.2, Duct Design.

ρ = density of air or gas in duct, kg/m^3
Δp_{se} = thermal gravity effect, Pa
Δp_t = total pressure change between sections 1 and 2, Pa
$\Delta p_{t,1\text{-}2}$ = total pressure loss caused by friction and dynamic losses plus thermal gravity effects between sections 1 and 2, Pa

1.1 HEAD AND PRESSURE

The terms **head** and **pressure** are often used interchangeably; however, head is the height of a fluid column supported by fluid flow, whereas pressure is the normal force per unit area. For liquids, it is convenient to measure head in terms of the flowing fluid. With a gas or air, however, it is customary to measure pressure exerted by the gas on a column of liquid.

Static Pressure

The term $p_s/\rho g$ is static head; p_s is static pressure.

Velocity Pressure

The term $V^2/2g$ refers to velocity head, and $\rho V^2/2$ refers to velocity pressure. Although velocity head is independent of fluid density, velocity pressure [Equation (8)] is not.

$$p_v = \rho V^2/2 \tag{8}$$

where

p_v = velocity pressure, Pa
V = fluid mean velocity, m/s

For air at standard conditions (1.204 kg/m^3), Equation (8) becomes

$$p_v = 0.602\ V^2 \tag{9}$$

Velocity is calculated by

$$V = Q/1000A \tag{10}$$

where

Q = airflow rate, L/s
A = cross-sectional area of duct, m^2

Total Pressure

Total pressure is the sum of static pressure and velocity pressure:

$$p_t = p_s + \rho V^2/2 \tag{11}$$

or

$$p_t = p_s + p_v \tag{12}$$

where

p_t = total pressure, Pa
p_s = static pressure, Pa

Pressure and Velocity Measurements

ASHRAE *Standard* 41.2-2018 provides procedures for measuring air pressure and velocity. It also describes the range, precision, and limitations of instruments used for these purposes. A manometer is a simple and useful means for measuring partial vacuum and low pressure. Static, velocity, and total pressures in a duct system relative to surrounding space pressures can be measured with a pitot tube connected to a manometer. Pitot tube construction and locations for traversing round and rectangular ducts are also presented in *Standard* 41.2-2018.

2. SYSTEM ANALYSIS

The total pressure change caused by friction, fittings, equipment, and net **thermal gravity effect** for each section of a duct system is calculated by the following equation:

$$\Delta p_{t_i} = \Delta p_{f_i} + \sum_{j=1}^{m} \Delta p_{ij} + \sum_{k=1}^{n} \Delta p_{ik} - \sum_{r=1}^{\lambda} \Delta p_{se_{ir}} \tag{13}$$

$$\text{for } i = 1, 2, \ldots, n_{up} + n_{dn}$$

where

Δp_{t_i} = net total pressure change for i sections, Pa
Δp_{f_i} = pressure loss caused by friction for i sections, Pa
Δp_{ij} = total pressure loss caused by j fittings, including fan system effect (FSE), for i sections, Pa
Δp_{ik} = pressure loss caused by k equipment for i sections, Pa
$\Delta p_{se_{ir}}$ = thermal gravity effect caused by r stacks for i sections, Pa
m = number of fittings within i sections
n = number of equipment within i sections
λ = number of stacks within i sections
n_{up} = number of duct sections upstream of fan (exhaust/return air subsystems)
n_{dn} = number of duct sections downstream of fan (supply air subsystems)

From Equation (7), the thermal gravity effect for each nonhorizontal duct with a density other than that of ambient air is determined by the following equation:

$$\Delta p_{se} = g(\rho_a - \rho)(z_2 - z_1) \tag{14}$$

where

Δp_{se} = thermal gravity effect, Pa
z_1 and z_2 = elevation from datum in direction of airflow (Figure 1), m
ρ_a = density of ambient air, kg/m^3
ρ = density of air or gas within duct, kg/m^3
g = 9.81 = gravitational acceleration, m/s^2

Example 1. For Figure 1, calculate the thermal gravity effect for two cases: (a) air cooled to –34°C, and (b) air heated to 540°C. Density of air at –34°C is 1.477 kg/m^3 and at 540°C is 0.434 kg/m^3. Density of ambient air is 1.204 kg/m^3. Stack height $z = z_2 - z_1$ is 15 m.

Solution:

$$\Delta p_{se} = 9.81(\rho_a - \rho)z$$

(a) For $\rho > \rho_a$ (Figure 1A),

$$\Delta p_{se} = 9.81(1.204 - 1.477)15 = -40 \text{ Pa}$$

(b) For $\rho < \rho_a$ (Figure 1B),

$$\Delta p_{se} = 9.81(1.204 - 0.434)15 = +113 \text{ Pa}$$

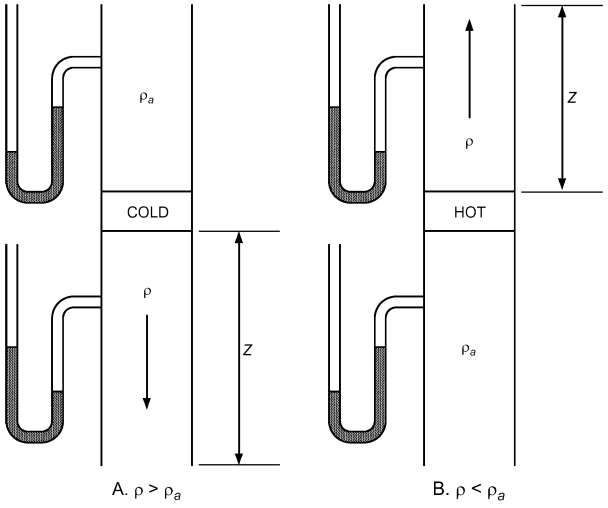

Fig. 1 Thermal Gravity Effect for Example 1

Licensed for single user. © 2021 ASHRAE, Inc.

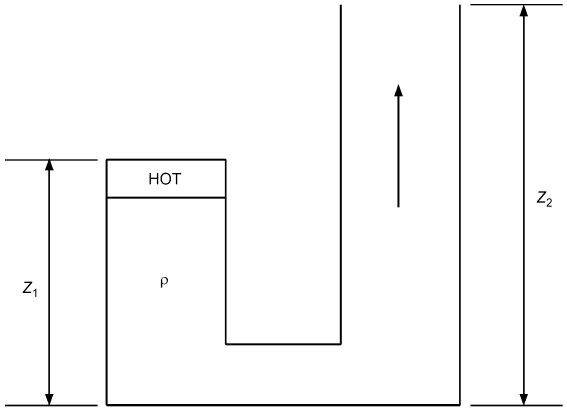

Fig. 2 Multiple Stacks for Example 2

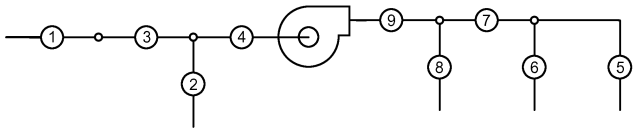

Fig. 3 Illustrative 6-Path, 9-Section System

Example 2. Calculate the thermal gravity effect for the two-stack system shown in Figure 2, where the air is 120°C and stack heights are 15 and 30 m. Density of 120°C air is 0.898 kg/m^3; ambient air is 1.204 kg/m^3.

Solution:

$$\Delta p_{se} = 9.81(\rho_a - \rho)(z_2 - z_1) = 9.81(1.204 - 0.898)(30 - 15) = 45 \text{ Pa}$$

To determine the fan total pressure requirement for a system, use the following equation:

$$P_t = \sum_{i \varepsilon F_{up}} \Delta p_{t_i} + \sum_{i \varepsilon F_{dn}} \Delta p_{t_i} \quad \text{for } i = 1, 2, \ldots, n_{up} + n_{dn} \qquad (15)$$

where

F_{up} and F_{dn} = sets of duct sections upstream and downstream of fan
P_t = fan total pressure, Pa
ε = symbol that ties duct sections into system paths from exhaust/return air terminals to supply terminals

Figure 3 shows the use of Equation (15). This system has three supply and two return terminals consisting of nine sections connected in six paths: 1-3-4-9-7-5, 1-3-4-9-7-6, 1-3-4-9-8, 2-4-9-7-5, 2-4-9-7-6, and 2-4-9-8. Sections 1 and 3 are unequal area; thus, they are assigned separate numbers in accordance with the rules for identifying sections (see step 5 in the section on HVAC Duct Design Procedures). To determine the fan pressure requirement, apply the following six equations, derived from Equation (15). These equations must be satisfied to attain pressure balancing for design airflow. Relying entirely on dampers is not economical and may create objectionable flow-generated noise.

$$\begin{cases} P_t = \Delta p_1 + \Delta p_3 + \Delta p_4 + \Delta p_9 + \Delta p_7 + \Delta p_5 \\ P_t = \Delta p_1 + \Delta p_3 + \Delta p_4 + \Delta p_9 + \Delta p_7 + \Delta p_6 \\ P_t = \Delta p_1 + \Delta p_3 + \Delta p_4 + \Delta p_9 + \Delta p_8 \\ P_t = \Delta p_2 + \Delta p_4 + \Delta p_9 + \Delta p_7 + \Delta p_5 \\ P_t = \Delta p_2 + \Delta p_4 + \Delta p_9 + \Delta p_7 + \Delta p_6 \\ P_t = \Delta p_2 + \Delta p_4 + \Delta p_9 + \Delta p_8 \end{cases} \qquad (16)$$

Example 3. For Figures 4A and 4C, calculate the thermal gravity effect and fan total pressure required when the air is cooled to –34°C. The heat exchanger and ductwork (section 1 to 2) total pressure losses are 170 and 70 Pa respectively. The density of –34°C air is 1.477 kg/m^3; ambient air is 1.204 kg/m^3. Elevations are 21 and 3 m.

Solution:

(a) For Figure4A (downward flow),

$$\Delta p_{se} = 9.81(\rho_a - \rho)(z_2 - z_1)$$
$$= 9.81(1.204 - 1.477)(3 - 21)$$
$$= 48 \text{ Pa}$$

$$P_t = \Delta p_{t,3-2} - \Delta p_{se}$$
$$= (170 + 70) - (48)$$
$$= 192 \text{ Pa}$$

(b) For Figure 4C (upward flow),

$$\Delta p_{se} = 9.81(\rho_a - \rho)(z_2 - z_1)$$
$$= 9.81(1.204 - 1.477)(21 - 3)$$
$$= -48 \text{ Pa}$$

$$P_t = \Delta p_{t,3-2} - \Delta p_{se}$$
$$= (170 + 70) - (-48)$$
$$= 288 \text{ Pa}$$

Example 4. For Figures 4B and 4D, calculate the thermal gravity effect and fan total pressure required when air is heated to 120°C. Heat exchanger and ductwork (section 1 to 2) total pressure losses are 170 and 70 Pa respectively. Density of 120°C air is 0.898 kg/m^3; ambient air is 1.204 kg/m^3. Elevations are 21 and 3 m.

Solution:

(a) For Figure 4B (downward flow),

$$\Delta p_{se} = 9.81(\rho_a - \rho)(z_2 - z_1)$$
$$= 9.81(1.204 - 0.898)(3 - 21)$$
$$= -54 \text{ Pa}$$

$$P_t = \Delta p_{t,3-2} - \Delta p_{se}$$
$$= (170 + 70) - (-54)$$
$$= 294 \text{ Pa}$$

(b) For Figure 4D (upward flow),

$$\Delta p_{se} = 9.81(\rho_a - \rho)(z_2 - z_1)$$
$$= 9.81(1.204 - 0.898)(21 - 3)$$
$$= 54 \text{ Pa}$$

$$P_t = \Delta p_{t,3-2} - \Delta p_{se}$$
$$= (170 + 70) - (54)$$
$$= 186 \text{ Pa}$$

Example 5. Calculate the thermal gravity effect for each section of the system shown in Figure 5, and the systems' net thermal gravity effect. Density of ambient air is 1.204 kg/m^3, and the lengths are as follows: z_1 = 15 m, z_2 = 27 m, z_4 = 30 m, z_5 = 8 m, and z_9 = 60 m. Pressure required at section 3 is –25 Pa. Write the equation to determine the fan total pressure requirement.

Solution: The following table summarizes the thermal gravity effect for each section of the system as calculated by Equation (14). The net thermal gravity effect for the system is 118 Pa. To select a fan, use the following equation:

$$P_t = 25 + \Delta p_{t,1\text{-}7} + \Delta p_{t,8\text{-}9} - \Delta p_{se} = 25 + \Delta p_{t,1\text{-}7} + \Delta p_{t,8\text{-}9} - 118 = \Delta p_{t,1\text{-}7} + \Delta p_{t,8\text{-}9} - 93$$

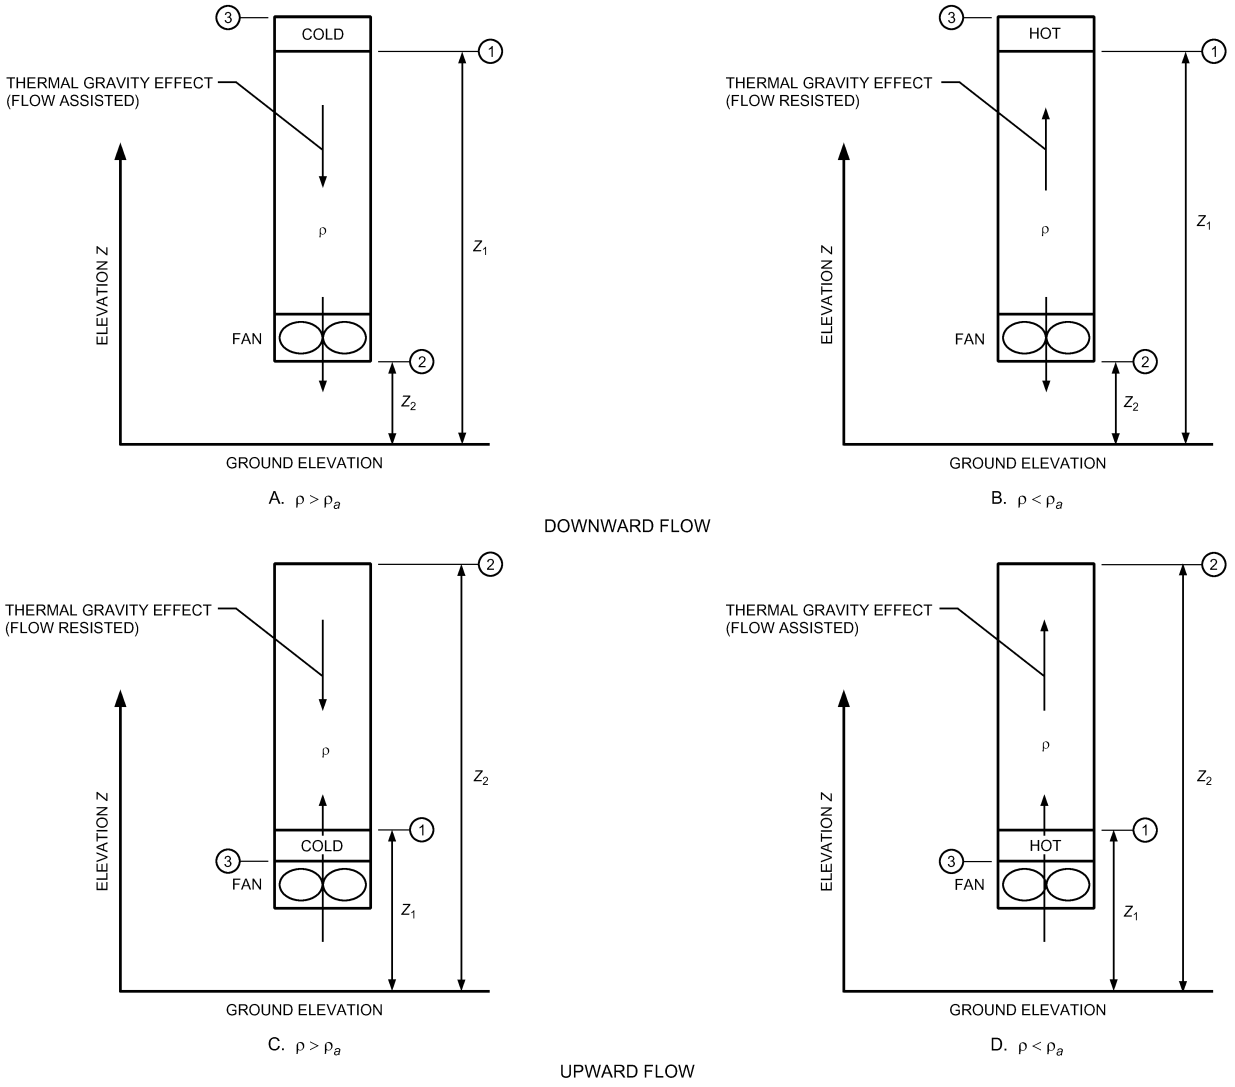

Fig. 4 Single Stack with Fan for Examples 3 and 4

Path (x–x')	Temp., °C	ρ, kg/m³	Δz ($z_{x'} - z_x$), m	$\Delta\rho$ ($\rho_a - \rho_{x-x'}$), kg/m³	Δp_{se}, Pa [Eq. (14)]
1-2	815	0.324	(27 – 15)	+0.880	+104
3-4	540	0.434	0	+0.770	0
4-5	540	0.434	(8 – 30)	+0.770	–166
6-7	120	0.898	0	+0.306	0
8-9	120	0.898	(60 – 0)	+0.306	+180
Net Thermal Gravity Effect					118

Airflow rate and direction depend on the sum of the stack, wind, and mechanically induced driving forces. Chapter 16 provides guidance on wind effects and on combining all of these driving forces.

2.1 PRESSURE CHANGES IN SYSTEM

Figure 6 shows total and static pressure changes in a fan/duct system consisting of a fan with both supply and return air ductwork. Also shown are total and static pressure gradients referenced to atmospheric pressure.

For all constant-area sections, total and static pressure losses are equal. At diverging transitions, velocity pressure decreases, absolute total pressure decreases, and absolute static pressure can in-

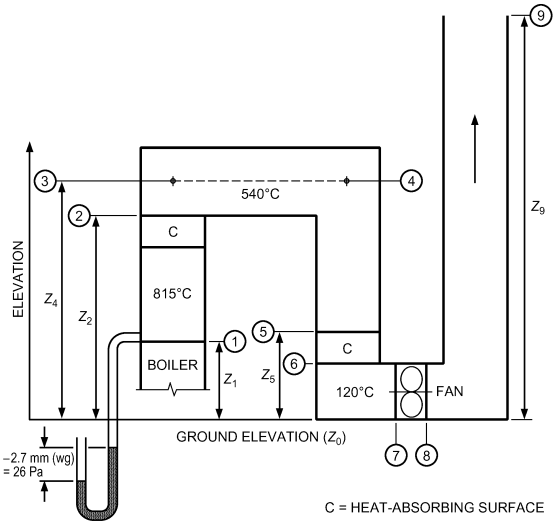

Fig. 5 Triple Stack System for Example 5

Licensed for single user. © 2021 ASHRAE, Inc.

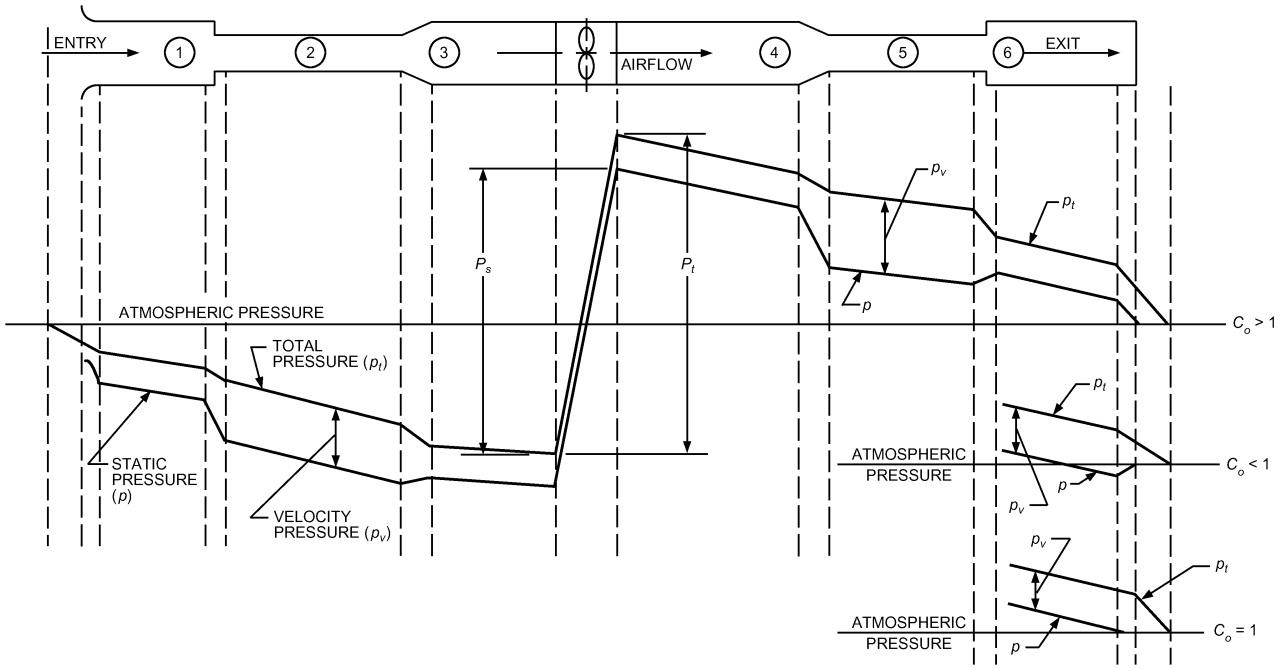

Fig. 6 Pressure Changes During Flow in Ducts

crease. The static pressure increase at these sections is known as **static regain**.

At converging transitions, velocity pressure increases in the direction of airflow, and absolute total and absolute static pressures decrease.

At the exit, total pressure loss depends on the shape of the fitting and the flow characteristics. Exit loss coefficients C_o can be greater than, less than, or equal to one. Total and static pressure grade lines for the various coefficients are shown in Figure 6. Note that, for a loss coefficient less than one, static pressure upstream of the exit is less than atmospheric pressure (negative). Static pressure just upstream of the discharge fitting can be calculated by subtracting the upstream velocity pressure from the upstream total pressure.

At section 1, total pressure loss depends on the shape of the entry. Total pressure immediately downstream of the entrance equals the difference between the upstream pressure, which is zero (atmospheric pressure), and loss through the fitting. Static pressure of ambient air is zero; several diameters downstream, static pressure is negative, equal to the sum of the total pressure (negative) and the velocity pressure (always positive).

System resistance to airflow is noted by the total pressure grade line in Figure 6. Sections 3 and 4 include fan system effect pressure losses. To obtain the fan static pressure rise requirement for selecting fans rated using this parameter (i.e., for fans with unducted outlets, such as plenum fans) and where fan total pressure rise is known, use

$$P_s = P_t - p_{v,o} \tag{17}$$

where

P_s = fan static pressure rise, Pa
P_t = fan total pressure rise, Pa
$p_{v,o}$ = fan outlet velocity pressure, Pa

Fan static pressure rise is also the difference between the fan outlet static pressure and the fan inlet total pressure ($p_{s,o} - p_{t,i}$). However, note that fan static pressure rise is not the difference in static pressure between the fan inlet and fan outlet, nor is it the sum of static pressure differences for components in the air-handling system.

3. FLUID RESISTANCE

Duct system losses are the irreversible transformation of mechanical energy into heat. The two types of losses are (1) friction and (2) dynamic.

3.1 FRICTION LOSSES

Friction losses are caused by shear stresses related to fluid viscosity. They result from adjacent fluid layers moving at different velocities. Turbulence also causes the fluid to transfer momentum, heat, and mass very rapidly across the flow. As a result, fluid velocities of the turbulent profile near the wall must drop to zero more rapidly than those of the laminar profile. In turn, friction losses are much greater in turbulent flow compared to laminar flow. Chapter 3 provides further details about ducted flows and friction losses. Friction losses occur along the entire duct length.

Darcy and Colebrook Equations

For fluid flow in conduits, friction loss can be calculated by the Darcy equation:

$$\Delta p_f = \frac{1000 f L}{D_h} \times \frac{\rho V^2}{2} \tag{18}$$

where

Δp_f = friction losses in terms of total pressure, Pa
f = friction factor, dimensionless
L = duct length, m
D_h = hydraulic diameter [Equation (24)], mm
V = velocity, m/s
ρ = density, kg/m^3

In the region of laminar flow (Reynolds numbers less than 2300), the friction factor is a function of Reynolds number only. For completely turbulent flow (fully rough), the friction factor depends on duct surface roughness and internal protuberances (e.g., joints). Between the bounding limits of hydraulically smooth behavior (laminar flow) and fully rough behavior is a transitional zone where the friction factor depends on both roughness and Reynolds number.

Licensed for single user. © 2021 ASHRAE, Inc.

In both the transitional and fully rough regions (see Moody diagram: Figure 13 in Chapter 3), the friction factor f is calculated by Colebrook's equation (Colebrook 1938-1939). Because Colebrook's equation cannot be solved explicitly for f, use iterative techniques to determine f (Behls 1971).

$$\frac{1}{\sqrt{f}} = -2 \log\left(\frac{\varepsilon}{3.7 D_h} + \frac{2.51}{\mathrm{Re}\sqrt{f}}\right) \quad (19)$$

where

ε = material absolute roughness factor, mm
Re = Reynolds number

Reynolds number (Re) is calculated using the following equation.

$$\mathrm{Re} = \frac{D_h V}{1000\ \nu} \quad (20)$$

where ν = kinematic viscosity, m^2/s.

For standard air and temperature between 4 and 38°C, Re can be calculated by

$$\mathrm{Re} = 66.4\ D_h V \quad (21)$$

Roughness Factors

Roughness factors listed in Table 1, column 3, are recommended for use with Equation (19). For increased calculation accuracy, use an absolute roughness factor from column 2.

Flexible Duct. For fully stretched and compressed flexible duct, use Equation (22) or Figure 7 (Abushakra et al. 2004; Culp 2011), where the multiplier PDCF is based on flexible duct with an absolute roughness ε = 0.9 mm. The resistance of flexible duct can be calculated using Fitting CD11-2 in the *ASHRAE Duct Fitting Database* (ASHRAE 2016). Flexible duct should be installed fully extended; its resistance even when fully extended is approximately 50% more compared to the resistance of an equivalent diameter rigid galvanized-steel spiral duct. See Example 6 for the increase in resistance of flexible duct fully stretched and compressed relative to rigid spiral duct.

For commercial systems, flexible ducts should be

- Limited to connections of rigid ducts to diffusers. For diffuser installation suggestions, see Figure 8. The purpose of limiting the offset to $D/8$ in Figure 8B is to minimize noise generation. Flexible duct should not be installed upstream of variable-air-volume (VAV) boxes.

Commentary: The loss coefficient or pressure loss for flexible duct elbows, such as those in Figure 8A, can be obtained from the *ASHRAE Duct Fitting Database* (ASHRAE 2016), Fitting CD3-22 (r/D = 1.0) or CD3-23 (r/D = 1.5). Loss coefficients are for fully stretched elbows.

- Limited to 2 m maximum, fully stretched.
- Installed without any radial compression.

Example 6. Compare the total pressure resistance of 250 mm, 1.8 m installed length, galvanized steel spiral and flexible duct, 0% compressed (fully stretched), 4%, 15%, and 30% compressed. Airflow is 470 L/s, air density is 1.204 kg/m^3, and absolute roughnesses ε of spiral round and flexible ducts are 0.12 mm and 0.9 mm. Calculate using the *ASHRAE Duct Fitting Database* [DFDB; ASHRAE (2016)].

Solution: See Table 2 for results.

$$\mathrm{PDCF} = 1 + 0.58\ K_c\ e^{-0.00496D} \quad (22)$$

with

$$K_c = \left(\frac{L_{FE} - L}{L_{FE}}\right) 100 \quad (23)$$

where

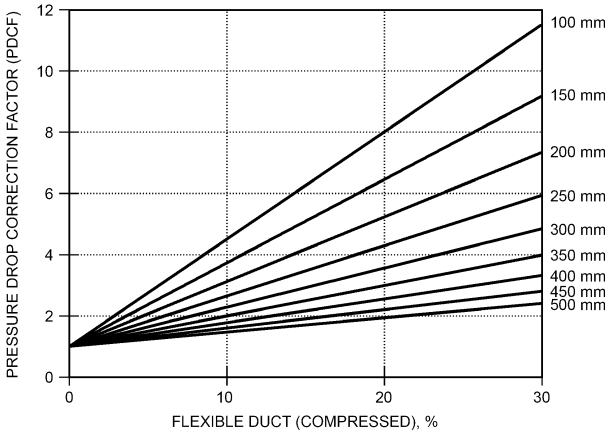
PDCF = pressure drop correction factor
K_c = flexible duct compressed, percent
D = flexible duct diameter, mm
L = installed duct length, m
L_{FE} = duct length fully extended, m

Friction Chart

The friction chart (Figure 9) is a plot of the Darcy and Colebrook equations [Equations (18) and (19), respectively], where the absolute roughness is 0.09 mm and the air is standard air (density = 1.204 kg/m^3)]. Figure 9 can be used for (1) duct construction/materials categorized as "average" in Table 1, (2) temperature variations of ±15 K from 20°C, (3) elevations to 500 m, and (4) duct pressures from –5 to +5 kPa relative to ambient pressure. These individual variations in temperature, elevation, and duct pressure result in duct losses within ±5% of the standard air friction chart.

The friction chart was changed in 1985 from an absolute roughness of 0.15 mm to 0.09 mm based on research by Griggs et al. (1987), who found that the roughness factor is affected by the material surface, joint spacing, and type of joint. The Wright friction chart appeared in the Handbook from 1946 to 1981. This chart was based on an absolute roughness ε = 0.15 mm, primarily because of the 760 mm joint spacing. In 1985 the friction chart was changed to ε = 0.09 mm because joint spacing was increasing. For the relative effect of straight duct resistance between charts, see Figure 10. For a 250 mm diameter duct at 10 m/s (491 L/s), the resistance decreased 5 to 6%.

Noncircular Ducts



A momentum analysis can relate average wall shear stress to pressure drop per unit length for fully developed turbulent flow in a passage of arbitrary shape but uniform longitudinal cross-sectional area. This analysis leads to the definition of **hydraulic diameter**:

$$D_h = 4A/P \quad (24)$$

where

D_h = hydraulic diameter, mm
A = duct area, mm^2
P = perimeter of cross section, mm

Although hydraulic diameter is often used to correlate noncircular data, exact solutions for laminar flow in noncircular passages show that this causes some inconsistencies. No exact solutions exist for

Pressure drop correction factor (PDCF) referenced to ε = 0.9 mm (medium rough) (Abushakra 2004; Culp 2011)

Fig. 7 Pressure Loss Correction Factor for Flexible Duct Not Fully Extended

Licensed for single user. © 2021 ASHRAE, Inc.

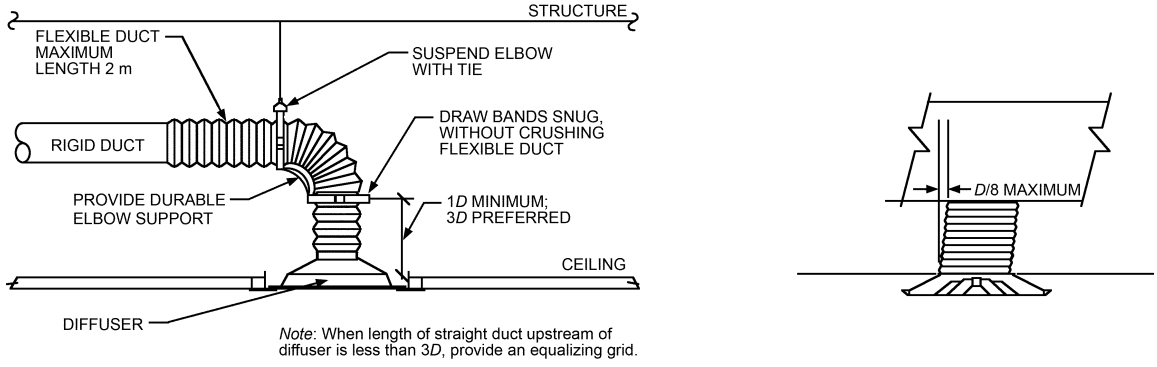


Table 1 Duct Roughness Factors

1	2	3
	Absolute Roughness ε, mm	
Duct Type/Material	**Range**	**Roughness Category**
Drawn tubing (Madison and Elliot 1946)	0.00046	Smooth 0.00046
PVC plastic pipe (Swim 1982)	0.009 to 0.046	Medium smooth 0.046
Commercial steel or wrought iron (Moody 1944)	0.046	
Aluminum, round, longitudinal seams, crimped slip joints, 0.91 m spacing (Hutchinson 1953)	0.037 to 0.061	
Friction chart:		
Galvanized steel, round, longitudinal seams, variable joints (Vanstone, drawband, welded. Primarily beaded coupling), 1.22 m joint spacing (Griggs et al. 1987)	0.049 to 0.098	Average 0.09
Galvanized steel, spiral seams, 3.05 m joint spacing (Jones 1979)	0.061 to 0.12	
Galvanized steel, spiral seam with 1, 2, and 3 ribs, beaded couplings, 3.66 m joint spacing (Griggs et al. 1987)	0.088 to 0.116	
Galvanized steel, rectangular, various type joints (Vanstone, drawband, welded. Beaded coupling), 1.22 m spacing[a] (Griggs and Khodabakhsh-Sharifabad 1992)	0.082 to 0.15	
Phenolic duct, aluminum foil on the interior face, sections connected with a four-bolt flange and cleat joint (Idem and Paruchuri 2018)		
1.52 m spacing:	0.149 to 0.391	
3.05 m spacing	0.075 to 0.298	
Wright Friction Chart:		
Galvanized steel, round, longitudinal seams, 0.76 m joint spacing, ε = 0.15 mm	Retained for historical purposes [See Wright (1945) for development of friction chart]	
Flexible duct, nonmetallic and wire, fully extended (Abushakra et al. 2004; Culp 2011)	0.09 to 0.9	Medium rough 0.9
Galvanized steel, spiral, corrugated,[b] Beaded slip couplings, 3.05 m spacing (Kulkarni et al. 2009)	0.54 to 0.91	
Fibrous glass duct, rigid (tentative)[c]	—	
Fibrous glass duct liner, air side with facing material (Swim 1978)	1.52	
Fibrous glass duct liner, air side spray coated (Swim 1978)	4.57	Rough 3.0
Flexible duct, metallic corrugated, fully extended	1.2 to 2.1	
Concrete (Moody 1944)	0.30 to 3.0	

[a]Griggs and Khodabakhsh-Sharifabad (1992) showed that ε values for rectangular duct construction combine effects of surface condition, joint spacing, joint type, and duct construction (cross breaks, etc.), and that the ε-value range listed is representative.
[b]Spiral seam spacing was 119 mm with two corrugations between seams. Corrugations were 19 mm wide by 6 mm high (semicircle).
[c]Subject duct classified "tentatively medium rough" because no data available.

Table 2 Solution for Example 6

Duct	DFDB Fitting	ε, mm	Airflow, L/s	Diameter, mm	Velocity, m/s	Compression, %	PDCF	Δp_t, Pa	% Δp_t Increased
Galvanized steel, spiral	CD11-1	0.12	470	250	9.6	NA	NA	7.7	Base
Flexible	CD11-2	0.9	470	250	9.6	(fully stretched)	1.0	11.4	48
Flexible	CD11-2	0.9	470	250	9.6	4	1.7	19.5	153
Flexible	CD11-2	0.9	470	250	9.6	15	3.5	40.0	419
Flexible	CD11-2	0.9	470	250	9.6	30	5.9	68.9	795

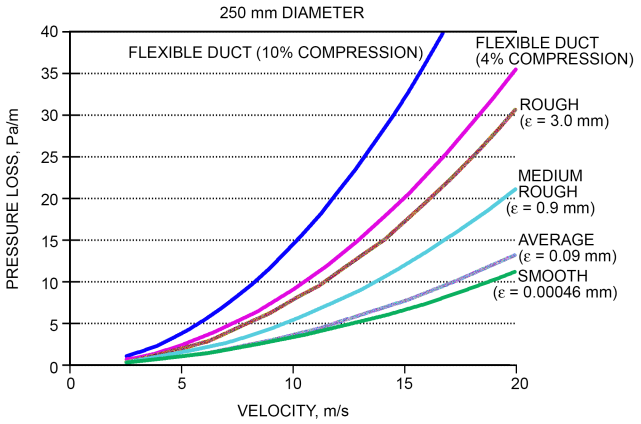

Fig. 10 Plot Illustrating Relative Resistance of Roughness Categories

turbulent flow. Tests over a limited range of turbulent flow indicated that fluid resistance is the same for equal lengths of duct for equal mean velocities of flow if the ducts have the same ratio of cross-sectional area to perimeter. From experiments using round, square, and rectangular ducts having essentially the same hydraulic diameter, Huebscher (1948) found that each, for most purposes, had the same flow resistance at equal mean velocities. Tests by Griggs and Khodabakhsh-Sharifabad (1992) also indicated that experimental rectangular duct data for airflow over the range typical of HVAC systems can be correlated satisfactorily using Equation (19) together with hydraulic diameter, particularly when a realistic experimental uncertainty is accepted. These tests support using hydraulic diameter to correlate noncircular duct data.

Rectangular Ducts. Huebscher (1948) developed the relationship between rectangular and round ducts that is used to determine size equivalency based on equal flow, resistance, and length. This relationship, Equation (25), is the basis for Table 3.

$$D_e = \frac{1.30\,(ab)^{0.625}}{(a+b)^{0.250}} \tag{25}$$

where

D_e = circular equivalent of rectangular duct for equal length, fluid resistance, and airflow, mm
a = length one side of duct, mm
b = length adjacent side of duct, mm

To determine equivalent round duct diameter, use Table 3. Equations (18) and (19) must be used to determine pressure loss.

Flat Oval Ducts. To convert round ducts to flat oval sizes, use Table 4, which is based on Equation (26) (Heyt and Diaz 1975), the circular equivalent of a flat oval duct for equal airflow, resistance, and length. Equations (18) and (19) must be used to determine friction loss.

$$D_e = \frac{1.55AR^{0.625}}{P^{0.250}} \tag{26}$$

where AR is the cross-sectional area of flat oval duct defined as

$$AR = (\pi a^2/4) + a(A - a) \tag{27}$$

and the perimeter P is calculated by

$$P = \pi a + 2(A - a) \tag{28}$$

where

P = perimeter of flat oval duct, mm
A = major axis of flat oval duct, mm
a = minor axis of flat oval duct, mm

3.2 DYNAMIC LOSSES

Dynamic losses result from flow disturbances caused by duct-mounted equipment and fittings that change flow direction (elbows), area changes (transitions), and converging/diverging junctions. For a detailed discussion of hydraulic networks, consult Idelchik et al. (1994).

Local Loss Coefficients

The dimensionless coefficient C is used for fluid resistance because this coefficient has the same value in dynamically similar streams (i.e., streams with geometrically similar stretches, equal Reynolds numbers, and equal values of other criteria necessary for dynamic similarity). The fluid resistance coefficient represents the ratio of total pressure loss to velocity pressure at the referenced cross section:

$$C = \frac{\Delta p_t}{\rho(V^2/2)} = \frac{\Delta p_t}{p_v} \tag{29}$$

where

C = local loss coefficient, dimensionless
Δp_t = total pressure loss, Pa
ρ = density, kg/m^3
V = velocity, m/s
p_v = velocity pressure, Pa

For all fittings, except junctions, total pressure loss is calculated by Equation (30):

$$\Delta p_t = C_o p_{v,o} \tag{30}$$

where

Δp_t = total pressure loss of fitting, Pa
C_o = local loss coefficient of fitting, dimensionless
$p_{v,o}$ = velocity pressure at section o of fitting, Pa

Dynamic loss is based on the actual velocity in the duct, not the velocity in an equivalent circular duct. For the cross section to reference a fitting loss coefficient, see step 5 in the section on HVAC Duct Design Procedures. Where necessary (e.g., unequal-area fittings), convert a loss coefficient from section o to section 1 using Equation (31), where V is the velocity at the respective sections.

$$C_1 = \frac{C_o}{(V_1/V_o)^2} \tag{31}$$

For converging and diverging flow junctions, total pressure loss through the straight (main) section is calculated by

$$\Delta p_{t,s} = C_s p_{v,s} \tag{32}$$

where

$\Delta p_{t,s}$ = total pressure loss across straight-through section s of junction, Pa
C_s = local loss coefficient referenced to s section of junction, dimensionless
$p_{v,s}$ = velocity pressure at section s, Pa

For total pressure loss through the branch section,

$$\Delta p_{t,b} = C_b p_{v,b} \tag{33}$$

where

$\Delta p_{t,b}$ = total pressure loss across branch b section of junction, Pa
C_b = local loss coefficient referenced to b section of junction, dimensionless
$p_{v,b}$ = velocity pressure at section b, Pa

*Table based on Equation (26).

The junction of two parallel streams moving at different velocities is characterized by turbulent mixing of the streams, accompanied by pressure losses. In the course of this mixing, particles moving at different velocities exchange momentum, resulting in equalization of the velocity distributions in the common stream. The jet with higher velocity loses part of its kinetic energy by transmitting it to the slower jet. The loss in total pressure before and after mixing is always large and positive for the higher-velocity jet, and increases with an increase in the amount of energy transmitted to the lower-velocity jet. Consequently, the local loss coefficient [Equation (29)] is always positive. Energy stored in the lower-velocity jet can increase because of mixing. The loss in total pressure and the local loss coefficient can, therefore, also have negative values for the lower-velocity jet (Idelchik et al. 1994).

Duct Fitting Database

Loss coefficients for more than 220 round, flat oval, and rectangular fittings are available in the *ASHRAE Duct Fitting Database* [DFDB; ASHRAE (2016)]. Also included are the pressure loss for round duct (CD11-1), flexible duct (CD11-2), rectangular duct

425	87.8	13.1	5.5	103.3	18.1	85.1	173.0

Δp_s = static pressure difference
Δp_t = total pressure difference at standard air conditions
$p_{v,in}$ = inlet velocity pressure at standard air conditions
$p_{v,out}$ = outlet velocity pressure at standard air conditions
Δp_v = velocity pressure difference at standard air conditions

(CR11-1), and flat oval (CF11-1) duct, as well as the following design tools:

- CD11-3, Straight Duct, Round, Velocity Limited
- CD11-4, Straight Duct, Round, Friction Rate Constant
- CD11-5, Straight Duct, Round, Minimum Velocity

Commentary: CD11-3 determines the size of a duct knowing airflow such that the design velocity is not exceeded. CD11-4 is for sizing duct systems by the equal friction method, knowing the design (target) friction rate and airflow. CD4-11 determines the duct size for industrial systems that must maintain a minimum velocity to convey particulates.

Example 8 uses CD11-3 in the equal friction and static regain designs, and CD11-4 for the equal friction design.

The fittings are numbered (coded) as shown in Table 5. Entries and converging junctions are only in the exhaust/return portion of systems. Exits and diverging junctions are only in supply systems. Equal-area elbows, obstructions, and duct-mounted equipment are common to both supply and exhaust systems. Transitions and unequal-area elbows can be either supply or exhaust fittings. Fitting ED5-1 is an **E**xhaust fitting with a round shape (**D**iameter). The number 5 indicates that the fitting is a junction, and 1 is its sequential number. Fittings SR31 and ER3-1 are **S**upply and **E**xhaust fittings, respectively. The R indicates that the fitting is **R**ectangular, and the 3 identifies the fitting as an elbow. Note that the cross-sectional areas at sections 0 and 1 are not equal. Otherwise, the elbow would be a **C**ommon fitting such as CR3-6.

Terminal Unit Loss Coefficients. Manufacturers' data for terminal units are not useful for duct design because they are given in terms of static pressure resistance and velocity pressure at standard air conditions (1.204 kg/m^3). The total pressure loss coefficient for the 200 mm terminal used in Example 7 is calculated from manufacturer's published data (Table 6: Columns 1, 2, and 7) and plotting $\Delta p_{v,in}$ versus Δp_t (Figure 11). The loss coefficient is 1.67 and is applicable for any elevation (air density). The total pressure loss (Δp_t) in Table 6 is only useful for projects at sea level. ASHRAE *Standard* 130-2016, Section 5.2, covers the laboratory test for total pressure loss and the calculation of the loss coefficient. In the *ASHRAE Duct Fitting Database* (ASHRAE 2016), the single-duct reheat VAV box is the CD8-series.

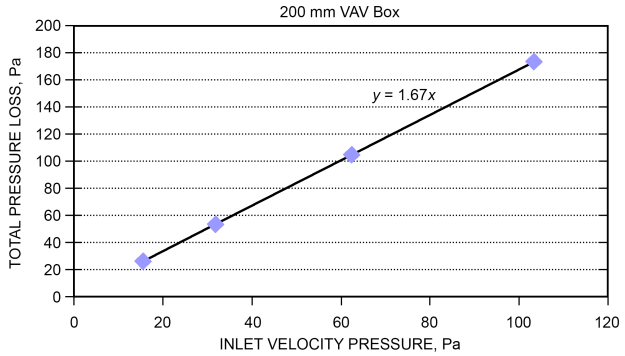

Fig. 11 VAV Box Loss Coefficient Plot

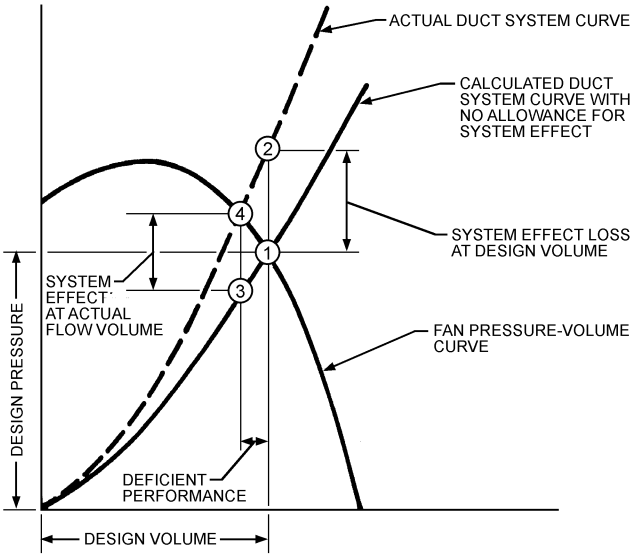

Fig. 12 Deficient System Performance with System Effect Ignored

3.3 DUCTWORK SECTIONAL LOSSES

Darcy-Weisbach Equation

Total pressure loss in a duct section is calculated by combining Equations (18) and (29) in terms of Δp, where ΣC is the summation of local loss coefficients in the duct section. Each fitting loss coefficient must be referenced to that section's velocity pressure.

$$\Delta p = \left(\frac{1000 f L}{D_h} + \Sigma C\right)\left(\frac{\rho V^2}{2}\right) \quad (34)$$

4. FAN/SYSTEM INTERFACE

Fan Inlet and Outlet Conditions

Fan performance data measured in the field may show lower performance capacity than manufacturers' ratings. The most com-

Licensed for single user. © 2021 ASHRAE, Inc.

mon causes of deficient performance of the fan/system combination are poor outlet connections, nonuniform inlet flow, and swirl at the fan inlet. These conditions alter the fan's aerodynamic characteristics so that its full flow potential is not realized. One bad connection can reduce fan performance below its rating.

Ducted fans are tested with several different configurations, depending on the fan type and intended applications. The configurations include open or ducted inlets and open or ducted outlets (AMCA *Standard* 210). Straight ducts are used when present. These setups result in uniform flow into and out of the fan. If good inlet and outlet conditions are not provided in the design of duct systems, fan performance suffers.

Figure 12 shows deficient fan performance resulting from poor fan inlet and outlet connections to adjacent ductwork. The system curve shown is typical of a constant-air-volume system without coils or air filters (e.g., a return or exhaust fan system). Point 1 is the fan/system operating point without taking into account poor inlet and/or outlet conditions. Point 2 is the system operating point when the apparent resistance of poor connections is included in the calculations. Point 4 is the operating point on the original fan performance curve, taking into consideration the apparent system resistance of poor fan/system connections. Point 3 is the fan operating point on the original system curve when the apparent resistance of poor inlet and/or fan connections is not taken into account. The airflow difference between points 2 and 4 represents the deficiency in airflow from design airflow.

Note that for some systems, particularly constant- or variable-volume air systems that include coils and filters and that may also control duct static pressures at some points, the system resistance curves can deviate substantially from that shown in Figure 12. Sherman and Wray (2010) provide more details about these types of systems and the resulting system curve shapes, including the effects of system leakage.

Fan System Effect Coefficients

The system effect concept was formulated by Farquhar (1973) and Meyer (1973); the magnitudes of the system effect, called **system effect factors**, were determined experimentally by the Air Movement and Control Association International (AMCA 2011a; Brown 1973; Clarke et al. 1978). The system effect factors, converted to local loss coefficients, are in the *ASHRAE Duct Fitting Database* (ASHRAE 2016) for both centrifugal and axial fans. Fan system effect coefficients are only an approximation. Fans of different types and even fans of the same type, but supplied by different manufacturers, do not necessarily react to a system in the same way. Therefore, judgment based on experience must be applied to any design.

Fan Outlet Conditions. Fans intended primarily for duct systems are usually tested with an outlet duct in place (AMCA *Standard* 210). Figure 13 shows the changes in velocity profiles at various distances from the fan outlet. For fully-developed flow, the duct, including transition, must meet the requirements for 100% effective duct length [L_e (Figure 13)], which is calculated as follows:

For $V_o > 13$ m/s,

$$L_e = \frac{V_o\sqrt{A_o}}{4500} \tag{35}$$

For $V_o \leq 13$ m/s,

$$L_e = \frac{\sqrt{A_o}}{350} \tag{36}$$

where

V_o = duct velocity, m/s
L_e = effective duct length, m
A_o = duct area, mm^2

Centrifugal fans should not abruptly discharge to the atmosphere. A diffuser design should be selected from Fitting SR7-2 or SR7-3. Consult the SR7-series fittings of the *ASHRAE Duct Fitting Database* (ASHRAE 2016) for guidance in the design of fan/ductwork connections.

Fan Inlet Conditions. For rated performance, air must enter the fan uniformly over the inlet area in an axial direction without prerotation. Nonuniform flow into the inlet is the most common cause of reduced fan performance. Such inlet conditions are not equivalent to a simple increase in system resistance, because they affect flow through the blade passages. Therefore, they cannot be treated as a percentage decrease in the flow and pressure from the fan. A poor inlet condition results in different fan performance.

Inlet spin may arise from many different approach conditions, and sometimes the cause is not obvious. Figure 14 shows some common duct connections that cause inlet spin. Inlet spin can be avoided by providing an adequate length of duct between the elbow and the fan inlet, as shown by Figure 15. Two L/D_o duct lengths upstream of the fan inlet reduces swirl and pressure loss (loss coefficient) by approximately 45% (Table 7).

Fans within plenums and cabinets or next to walls should be located so that air may flow unobstructed into the inlets. Fan performance is reduced if the space between the fan inlet and the enclosure is too restrictive. System effect coefficients for fans in an enclosure or adjacent to walls are listed under Fitting ED7-1. How the airstream enters an enclosure in relation to the fan inlets also affects fan performance. Plenum or enclosure inlets or walls that are not symmetrical with the fan inlets cause uneven flow and/or inlet spin.

5. MECHANICAL EQUIPMENT ROOMS

In the initial phase of building design, the design engineer seldom has sufficient information to render the optimum HVAC design for the project, and its space requirements are often based on percentage of total area or other rule of thumb. The final design is usually a compromise between what the engineer recommends and what the architect can accommodate. Total mechanical and electrical space requirements range between 4 and 9% of gross building area, with most buildings in the 6 to 9% range. This range includes space for HVAC, electrical, plumbing, and fire protection equipment, as well as vertical shaft space for mechanical and electrical distribution through the building.

Outdoor Air Intake and Exhaust Air Discharge Locations

A key factor in the location of mechanical equipment rooms is the source of outdoor air. If the air intake or exhaust system is not well designed, contaminants from nearby outdoor sources (e.g., vehicle exhaust) or from the building itself (e.g., laboratory fume hood exhaust) can enter the building with insufficient dilution. Poorly diluted contaminants may cause odors, health impacts, and reduced indoor air quality. Examples are toxic stack exhausts, automobile and truck traffic, kitchen cooking hoods, evaporative cooling towers, building general exhaust air, trash dumpsters, stagnant water bodies, snow and leaves, rain and fog, plumbing vents, vandalism, and terrorism.

Chapter 46 of the 2019 *ASHRAE Handbook—HVAC Applications* discusses proper design of exhaust stacks and placement of air intakes to avoid adverse air quality impacts. Experience provides some general guidelines on air intake placement. Unless dispersion modeling analysis is conducted, air intakes should never be located on the roof in the same architectural screen enclosure as exhaust

outlets. If exhaust is discharged from several locations on the roof, intakes should be located to minimize contamination. Typically, this means maximizing separation distance. Where all exhausts of concern are emitted from a single, relatively tall stack or tight cluster of stacks, a possible intake location might be close to the base of this tall stack, if this location is not adversely affected by other exhaust locations, or is not influenced by tall adjacent structures creating downwash. Architectural screens placed around rooftop equipment to reduce noise or hide equipment interact with the windflow patterns on the roof and can adversely affect exhaust dilution. Chapter 46 of the 2019 *ASHRAE Handbook—HVAC Applications* describes a method to account for these screens by modifying the physical stack height.

When wind is perpendicular to the upwind wall, air flows up and down the wall, dividing at about two-thirds up the wall. The downward flow creates ground-level swirl that stirs up dust and debris. To take advantage of the natural separation of wind over the upper and lower halves of a building, toxic or nuisance exhausts should be located on the roof and intakes on the lower one-third of the building, but high enough to avoid wind-blown dust, debris, and vehicle exhaust. If ground-level sources are major sources of contaminants, rooftop intake is desirable.

Buildings over three stories usually require vertical shafts to consolidate mechanical, electrical, and telecommunication distribution through the facility. Vertical shafts should be located in or adjacent to mechanical/fan rooms and as far as possible from noise-sensitive areas. In general, duct shafts with an aspect ratio of 2:1 to 4:1 are easier to develop than large square shafts. The rectangular shaft also facilitates transition from equipment in the fan rooms to the shaft.

Fan rooms in a basement or at street level should be avoided. These locations are a security concern because harmful substances could easily be introduced. Using louvers at these locations is also a concern because debris, leaves, and snow may fill the area, resulting in safety, health, and fan performance concerns. Loading docks and nearby parking areas may also compromise ventilation air quality.

Equipment Room Locations

Mechanical equipment rooms, including air-handling units, should be centrally located to centralize maintenance and operation. But, for many reasons, not all equipment rooms can be centrally located in the building. In any case, equipment should be kept together whenever possible to minimize space requirement, centralize maintenance and operation, and simplify electrical systems. All HVAC air system equipment rooms should have space for maintaining equipment and the replacement of fans, coils and other key equipment.

High-rise buildings may opt for decentralized fan rooms for each floor, or for more centralized service with one mechanical/fan room serving the lower 10 to 20 floors, one serving the middle floors of the building, and one at the roof serving the top floors.

Decentralized Equipment Rooms. Locate decentralized mechanical equipment rooms as far as possible from noise-sensitive areas, and surround equipment rooms with buffer zones such as toilet and storage rooms, as well as elevator, stair, and duct shafts. Figure 16 shows various core locations from poor to best. The number of decentralized fan rooms required depends largely on total floor area and any fan system power limitation imposed by codes or standards (e.g., ASHRAE *Standard* 90.1-2019, section 6.5.3.1). When decentralized air systems are located centrally to the spaces served, duct systems are shorter, occupy less volume, use less power, are quieter, and are less expensive. Pointing out these advantages can often help to convince architects to make desirable decentralized locations available.

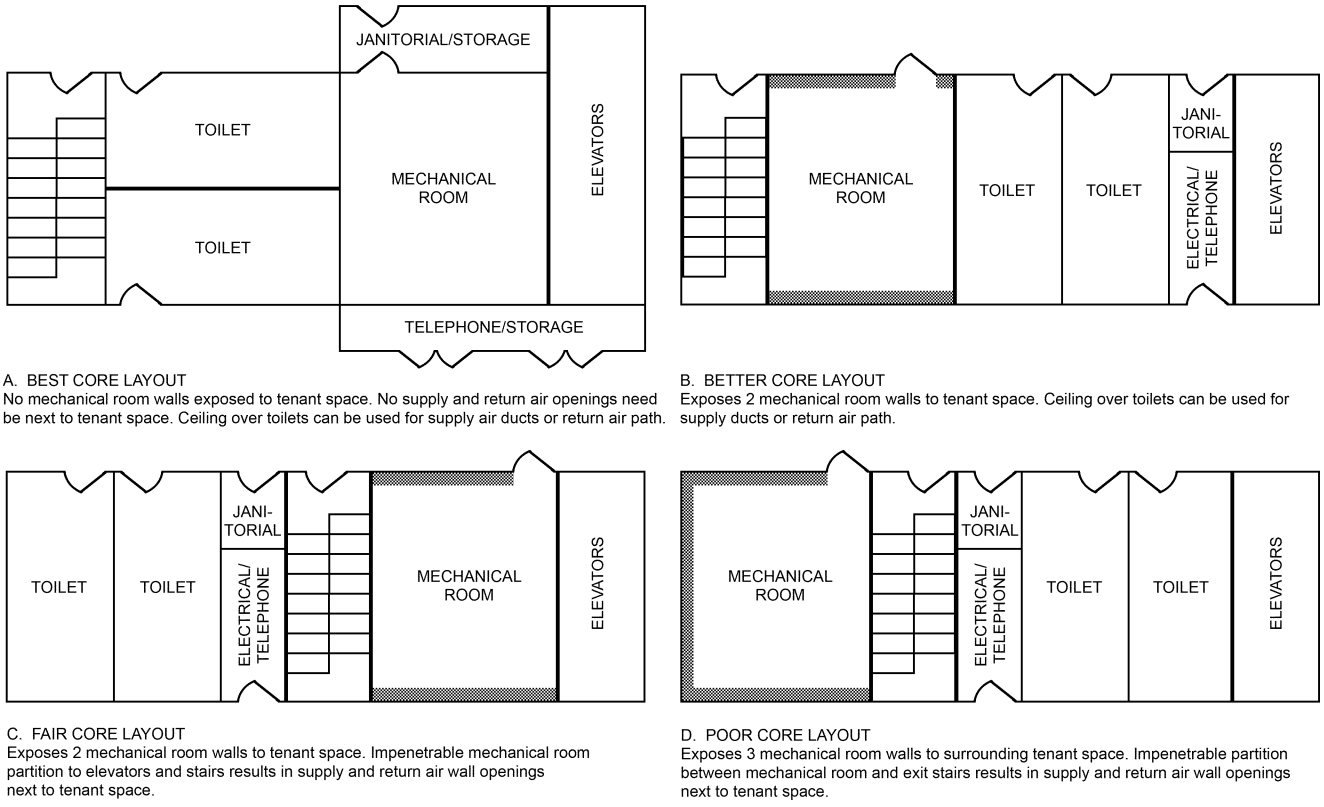
6. DUCT DESIGN

6.1 DESIGN CONSIDERATIONS

HVAC System Air Leakage

See Chapter 19 of the 2020 *ASHRAE Handbook—HVAC Systems and Equipment* for (1) sealant specifications, and (2) the rationale for HVAC system sealing and leakage testing.

System Sealing. All ductwork and plenum transverse joints, longitudinal seams, and duct penetrations should be sealed. Longitudinal seams are joints in the direction of airflow. Transverse joints are connections of two duct sections, with the connections oriented perpendicular to airflow. Openings for rotating shafts, wires, and pipes or tubes should be sealed with bushings or other devices that minimize air leakage but that do not interfere with shaft rotation or prevent thermal expansion. Spiral lock seams need not be sealed. Duct-mounted equipment, such as terminal units, reheat coils, access doors, sound attenuators, balancing dampers, control dampers, and fire dampers, should be specified as low leakage so that the system can meet the air leakage acceptance criteria set by the designer, standards, and codes. Recommended specifications for duct-mounted equipment are provided later in this section.



Sealing that would void product listings (e.g., for fire/smoke or volume control dampers) is not required. However, low-leakage duct-mounted components, including terminal units, reheat coils, and access doors, should be specified so that the combined HVAC system air leakage will not exceed criteria set by the designer, ASHRAE *Handbook*, standards, and codes. For example, some UL-listed and UL-labeled fire/smoke dampers allow sealing and gasketing of breakaway duct/sleeve connections; all can provide sealed non-breakaway duct/sleeve connections.

Scope. It is recommended that supply air (both upstream and downstream of the VAV box primary air inlet damper when used) and independent exhaust air systems or selected parts thereof be tested for air leakage after construction *at operating conditions* using ASHRAE *Standard* 215 (ASHRAE 2018) to verify (1) good workmanship, and (2) the use of low-leakage components as required to achieve the design allowable system air leakage. Testing these particular systems is important because of the potentially significant energy impacts caused by air leakage to or from them. As a minimum, 25% of the system based on duct surface area should be tested, and an additional 25% should be tested if any of the initial sections fail. If any section of the second 25% fails, the entire system should be tested. Sections to be tested should be selected randomly by the owner's representative. These leakage tests should be conducted by an independent party responsible to the owner's representative after the system sections to be tested are fully assembled but before the installation of insulation and concealment of ductwork. To ensure that a system passes its air leakage test at operating conditions, sufficient ductwork sections should be leak tested by pressurization during construction to vet construction techniques. To supplement these construction phase tests, leakage of duct-mounted components should be determined by specification and certified leakage data provided with equipment submittals. Leakage of air-handling units should be determined by specification and verification leakage tests.

Independent exhaust air system: air discharged from a space to the outdoors by a system not coupled to supply or return air systems.

Acceptance Criteria. To enable proper accounting of leakage-related impacts on fan energy and space conditioning loads, the allowable system air leakage for each fan system test section should be established by the design engineer as a percentage of fan airflow entering the test section at a reference operating condition. The method of test in ASHRAE *Standard* 215-2018 includes how to

Licensed for single user. © 2021 ASHRAE, Inc.

A. BEST CORE LAYOUT
No mechanical room walls exposed to tenant space. No supply and return air openings need be next to tenant space. Ceiling over toilets can be used for supply air ducts or return air path.

B. BETTER CORE LAYOUT
Exposes 2 mechanical room walls to tenant space. Ceiling over toilets can be used for supply ducts or return air path.

C. FAIR CORE LAYOUT
Exposes 2 mechanical room walls to tenant space. Impenetrable mechanical room partition to elevators and stairs results in supply and return air wall openings next to tenant space.

D. POOR CORE LAYOUT
Exposes 3 mechanical room walls to surrounding tenant space. Impenetrable partition between mechanical room and exit stairs results in supply and return air wall openings next to tenant space.

Fig. 16 Comparison of Various Mechanical Equipment Room Locations
(Schaffer 2011)

establish a reference operating condition, but because it is not a rating standard, it does not provide system air leakage acceptance criteria. However, as described in Chapter 19 of the 2020 *ASHRAE Handbook—HVAC Systems and Equipment*, the recommended maximum system leakage is 5% of design airflow. Exceptions: supply and return ductwork sections that leak directly to/from outdoors and exhaust system ductwork sections that draw in indoor air through leaks should be limited to 2%.

Equation (37) is for use in a leakage test during construction to ensure that ductwork will meet the leakage specification. This equation translates system fractional air leakage to test section leakage class, as specified by ASHRAE *Standard* 90.1-2019, section 6.4.4.2.2.

$$C_{L,\,section} = \frac{(Q_{leak,\,frac}/100)(Q_{fan}/A_{system})}{\Delta p_{section}^{0.65}} \tag{37}$$

where

$C_{L,section}$ = test section leakage class, L/s per Pa$^{0.65}$ per square metre of duct surface area
Q_{fan} = maximum fan airflow that would occur during operation, L/s}
$Q_{leak,\,frac}$ = system leakage fraction corresponding to maximum fan airflow that would occur during operation, %
A_{system} = total system duct surface area, m^2
$\Delta p_{section}$ = test section static pressure difference corresponding to maximum fan airflow that would occur during operation, Pa

Equation (37) shows that leakage class depends on fractional air leakage and normalized fan airflow (Q_{fan}/A_{system}), and varies inversely with the pressure difference raised to the 0.65 power. For example, to achieve 3% leakage for ductwork with Q_{fan}/A_{system} = 10 L/s per m^2 of duct surface area and $\Delta p_{section}$ = 750 Pa, the required leakage class is 0.004 L/s per Pa$^{0.65}$ per square metre of duct surface area. With $\Delta p_{section}$ =125 Pa instead (six times less), the required leakage class is about three times greater (0.13).

The maximum acceptable air leakage for a test section corresponding to the leakage class determined by Equation (37) can be expressed by Equation (38).

$$Q_{leak,\,section} = C_{L,\,section} A_{section} / \Delta p_{section}^{0.65} \tag{38}$$

where

where

$Q_{leak,section}$ = test section air leakage, L/s
$A_{section}$ = test section duct surface area, m^2

Equations (37) and (38) can be combined so that the maximum acceptable air leakage for a test section during construction is simply a function of system fractional leakage, normalized fan airflow (Q_{fan}/A_{system}), and section duct surface area:

$$Q_{leak,\,section} = \left(\frac{Q_{leak,\,frac}}{100}\right)(Q_{fan}/A_{system})\,A_{section} \tag{39}$$

Thus, for air leakage tests *during construction*, the maximum acceptable leakage for a ductwork section is given by Equation (38) or (39). Duct surface area should be calculated in accordance with European *Standard* EN 14239. The test pressure for each section should be specified by the design engineer based on the maximum static pressure for that section that would occur during operation at maximum fan airflow.

Example 7. The system depicted by Figure 17 has the characteristics summarized by Table 8. For a maximum acceptable leakage of 3% of the 2360 L/s maximum fan airflow, which is 71 L/s total, what is the maximum allowable ductwork leakage in (1) each section that is to be

Licensed for single user. © 2021 ASHRAE, Inc.

tested at the pressures noted, and (2) sections 4 and 5 when leak tested together?

Solution: The calculations and maximum allowable leakage are also summarized in Table 8. Note that adjacent sections with the same static pressure can be grouped for leakage testing. In this case, Sections 4 and 5 can be grouped. The allowable leakage for Sections 4 and 5 when tested individually is 4 L/s and 20 L/s respectively. The allowable leakage for Sections 4 and 5 when tested together is 24 L/s.

Recommended Specification for Duct-Mounted Equipment. Duct-mounted component leakage is controlled by specification and certified leakage data provided with equipment submittals. The following are recommended leakage-related specifications for duct-mounted equipment.

- **Terminal Units.** Seal longitudinal seams of casings, inlet face of casings, and inlet collars with mastic. Seal damper shaft penetrations of casings. Casing leakage for the basic terminal unit should not exceed 2.1 L/s at 249 Pa static pressure differential. Terminal unit leakage with an access door should not exceed 2.2 L/s at 249 Pa. Testing should be by an accredited laboratory. Leakage tests should comply with ASHRAE *Standard* 130.

  Access doors in terminal unit casings should comply with AMCA *Standard* 500-D, and leakage rates should be certified per AMCA (2013) *Publication* 511. Access door (frame not included) leakage should not exceed 0.24 L/s at 2.49 kPa static pressure differential.
- **Electric Reheat Coils.** Flange-mount electric coils with a gasket. Coil leakage should not exceed 0.24 L/s at 249 Pa static pressure differential. Tests should be by an accredited laboratory. Leakage tests should be in compliance with ASHRAE *Standard* 126-2016 (ASHRAE 2016).
- **Hot-Water Reheat Coils.** Flange-mount hot-water coils with a gasket in an insulated plenum or casing. Seal all seams and casing penetrations for supply and return water tubes. Coil casing leakage (not counting transverse joints) should not exceed 0.24 L/s at 249 Pa static pressure differential. An accredited laboratory should perform leakage tests in compliance with ASHRAE *Standard* 126.

Table 8 Solution for Example 7

Section	Section Inlet Flow, L/s	$A_{section}$, m²	Section Static Pressure, Pa	Section Leakage Class, L/s per m² per Pa$^{0.65}$	Section Allowable Leakage, L/s
		Input		Equation (37)	Equation (38) or (39)
1	2 360	46.5	750	0.003	10
2	944	62.0	250	0.006	14
3	1 416	69.7	500	0.004	15
4	472	18.6	250	0.006	4
5	944	92.9	250	0.006	20
Total		289.6			63
4 and 5	1 416	111.5	250	0.006	24

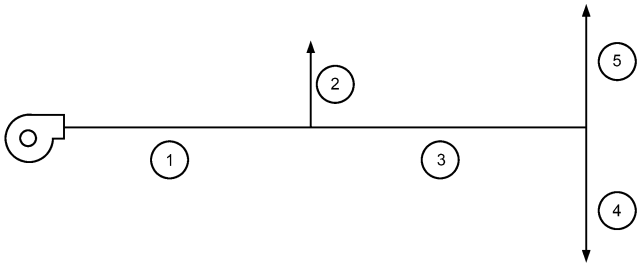


Fig. 17 Duct Layout for Example 7

- **Access Doors.** Access door leakage (excluding the frame) should not exceed 0.24 L/s at 2.49 kPa static pressure differential. Leakage tests should comply with AMCA *Standard* 500-D, and leakage rates certified per AMCA (2013) *Publication* 511.
- **Attenuators.** Sound attenuator casing seams should be sealed at the factory if used in-line with the ductwork. Attenuators stacked in plenums do not have to be sealed, but plenums should be sealed.
- **Fire/Smoke Dampers.** These dampers should be installed in accordance with the manufacturer's UL installation instructions. Each fire damper should be furnished with a UL-approved sleeve. Sleeve seams should be continuously welded or sealed, and the transverse joint should be a sealed UL-approved flanged duct sleeve connection (break-away or non-break-away).
- **Balancing Dampers.** Balancing damper casing seams should be continuously welded or sealed, and the shaft penetrating the casing should have seals.
- **Control Dampers.** Control damper shafts penetrating ducts should have seals.

Recommended Specification for Air-Handling Units. Refer to Chapter 19 of the 2020 *ASHRAE Handbook—HVAC Systems and Equipment* for leakage-related specifications for air-handling units.

Responsibilities. The **engineer** should

- Specify HVAC system components, duct-mounted equipment, sealants, and sealing procedures that together will meet the system airtightness design objective.
- Inspect the system during construction for quality of workmanship and to verify that correct duct-mounted components and air-handling units are installed.
- Specify the *construction-stage* ductwork leakage test standard or procedures.
- Specify the *construction-stage* test pressures to the nearest 25 Pa expected during operation at design conditions and the maximum allowable air leakage.
- Review and approve the sheet metal and test contractors' leakage test reports. If any system has a leakage failure, the engineer should discuss remedies with the sheet metal contractor, vendor, and/or owner's representative.

The **sheet metal contractor** should

- Construct the system using quality workmanship and correct duct-mounted components and air-handling units. If any installed duct-mounted equipment appears to be leakage suspect, the contractor should discuss remedies with the engineer and/or owner's representative.
- Conduct *ductwork* leakage pressurization tests *during construction*. As a minimum, 25% of the ductwork system (based on duct surface area) should be tested during construction, and another 25% if any of the initial sections fail. If any section of the second 25% fails, the entire ductwork system should be leak tested.
- Provide connections for test apparatus, and separate test sections from each other as needed so that the test apparatus capacity is not exceeded.
- Report test results and, where required, take corrective action to seal ductwork and absorb the cost for conducting related additional leak tests.

The **test contractor** should

- Conduct the *operating system* leakage test in compliance with ASHRAE *Standard* 215-2018.
- Report test results, including reasons for any failures.

It should be the responsibility of the **owner or owner's representative** to provide direction upon request.

Fire and Smoke Control

Because duct systems can convey smoke, hot gases, and fire from one area to another and can accelerate a fire within the system, fire protection is an essential part of air-conditioning and ventilation system design. Generally, fire safety codes require compliance with the standards of national organizations. NFPA *Standard* 90A examines fire safety requirements for (1) ducts, connectors, and appurtenances; (2) plenums and corridors; (3) air outlets, air inlets, and fresh air intakes; (4) air filters; (5) fans; (6) electric wiring and equipment; (7) air-cooling and -heating equipment; (8) building construction, including protection of penetrations; and (9) controls, including smoke control.

Fire safety codes often refer to the testing and labeling practices of nationally recognized laboratories, such as Factory Mutual and Underwriters Laboratories (UL). UL's annual *Building Materials Directory* lists fire and smoke dampers that have been tested and meet the requirements of UL *Standards* 555 and 555S. This directory also summarizes maximum allowable sizes for individual dampers and assemblies of these dampers. Fire dampers are 1.5 h or 3 h fire-rated. Smoke dampers are classified by (1) temperature degradation [ambient air or high temperature (120°C minimum)] and (2) leakage at 250 and 1000 Pa pressure difference (2 and 3 kPa classification optional). Smoke dampers are tested under conditions of maximum airflow. UL's annual *Fire Resistance Directory* lists fire resistances of floor/roof and ceiling assemblies with and without ceiling fire dampers.

For a more detailed presentation of fire protection, see the NFPA (2008) *Fire Protection Handbook*, Chapter 54 of the 2019 *ASHRAE Handbook—HVAC Applications*, and Klote et al. (2012).

Duct Insulation

In all new construction (except low-rise residential buildings), air-handling ducts and plenums that are part of an HVAC air distribution system should be thermally insulated in accordance with ASHRAE *Standard* 90.1. Duct insulation for new low-rise residential buildings should comply with ASHRAE *Standard* 90.2. Existing buildings should meet requirements of ASHRAE *Standard* 100. In all cases, thermal insulation should meet local code requirements. Insulation thicknesses in these standards are minimum values; economic and thermal considerations may justify higher insulation levels. Additional insulation, vapor retarders, or both may be required to limit vapor transmission and condensation.

Duct heat gains or losses must be known to calculate supply air quantities, supply air temperatures, and coil loads. To estimate duct heat transfer and entering or leaving air temperatures, refer to Chapters 4 and 23.

Physical Security

Ducts entering into spaces considered secured or sensitive should contain measures to detect or inhibit forced entry into those spaces through the duct system. Inhibiting measures should be based on a delay or resistance time set by the facility owner or user. The following security measures should be considered:

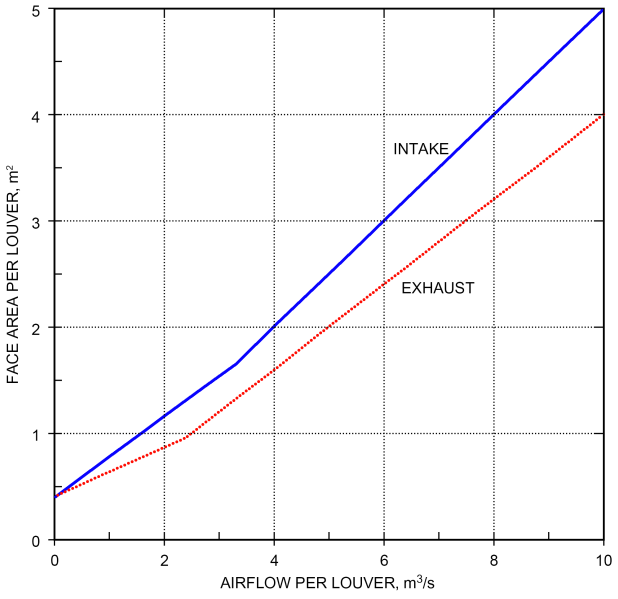
- **Barrier duct bars:** placement should be at locations deemed appropriate by the facility owner and user, or where secured or sensitive area boundaries exist (e.g., duct penetration through the wall of a secured room). Bar diameter, material, and spacing should be established by the facility owner or user. Ensure that barriers do not inhibit proper operation and maintenance of dampers, detectors, sensors, and other devices in the duct system.
- **Welded diffuser and return grilles:** grille material and spacing should be established by the facility owner or user.
- **Sensors on access doors:** sensors should be connected to a facility security system or panel, and notify security personnel of a duct system breach. Communicating HVAC maintenance schedules to security personnel is necessary to ensure that an intrusive duct system breach is not confused with HVAC system maintenance.

Louvers

Use Figure 18 for preliminary sizing of air intake and exhaust louvers. For air quantities greater than 3300 L/s per louver, the air intake gross louver openings are based on 2 m/s; for exhaust louvers, 2.5 m/s is used for air quantities of 2400 L/s per louver and greater. For smaller air quantities, see Figure 18. These criteria are presented on a per-louver basis (i.e., each louver in a bank of louvers) to include each louver frame. Representative production-run louvers were used in establishing Figure 18, and all data used were based on AMCA *Standard* 500-L tests. For louvers larger than 1.5 m^2, the free areas are greater than 45%; for louvers less than 1.5 m^2, free areas are less than 45%. Unless specific louver data are analyzed, no louver should have a face area less than 0.4 m^2. If debris can collect on the screen of an intake louver, or if louvers are located at grade with adjacent pedestrian traffic, louver face velocity should not exceed 0.5 m/s.

Louvers require special treatment because the blade shapes, angles, and spacing cause significant variations in louver-free area and performance (pressure drop and water penetration). Selection and analysis should be based on test data obtained from the manufacturer in accordance with AMCA *Standard* 500-L, which presents both pressure drop and water penetration test procedures and a uniform method for calculating the free area of a louver. Tests are conducted on a 1220 mm square louver with the frame mounted flush in the wall. For water penetration tests, rainfall is 100 mm/h, no wind, and the water flow down the wall is 0.05 L/s per linear metre of louver width.

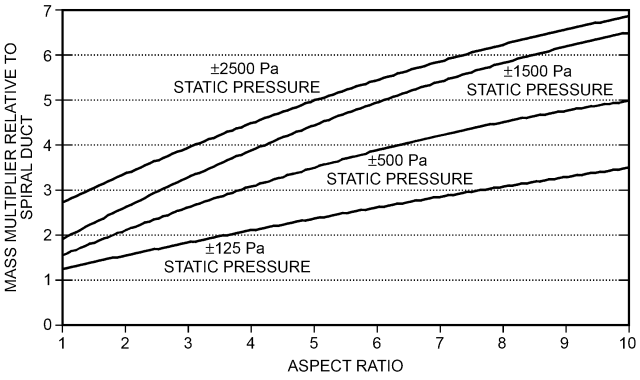
AMCA *Standard* 500-L also includes a method for measuring water rejection performance of louvers. These louvers are subjected to simulated rain and wind pressure and tested at a rainfall of 76 mm/h falling on the louver's face with a predetermined wind velocity directed at the face of the louver (typically 13 or 20 m/s). Effectiveness ratings are assigned at various airflow rates through the louver.



Duct Shape Selection

No Space Constraints. Round ductwork is preferable to rectangular or flat oval ductwork when adequate space is available for the following reasons.

- **Mass** of round ductwork is less than rectangular. Figure 19 shows the relative weight of rectangular duct to round duct for duct pressures from ±125 to ±2500 Pa when the equivalent diameter of the rectangular duct is the same as the round duct diameter. Equivalent diameter is defined as the diameter of a rectangular duct that has equal resistance to flow for equal flow and length.
- **Perimeter** of round ducts is less than rectangular ducts**.** For rectangular duct aspect ratios from 2 to 4, the increase is approximately 30 to 55%. This increase results in increased insulation, including possible thickness to offset the additional heat transfer. For a comprehensive study of round and rectangular ducts as they affect system performance, consult McGill (1988).
- Round ducts have an excellent resistance to **low-frequency breakout noise** (Schaffer 2011).
- Duct **rumble** can occur in rectangular duct systems (Paulauskis 2016).



Space Constraints. Space constraints and obstructions, particularly ceiling height, are frequent problems. In these cases, the choice is round, rectangular, or flat oval ducts, depending on the air quantity that needs to be conveyed by the duct. Table 9 and Figure 20 cover three design cases: 0.65, 2, and 5 Pa/m friction rates. Friction rate 2

Licensed for single user. © 2021 ASHRAE, Inc.

Parameters Used to Establish Figure	Intake Louver	Exhaust Louver
Minimum free area (1220 mm square test section), %	45	45
Water penetration, mL/(m²·0.25 h)	Negligible (less than 0.3)	N/A
Maximum static pressure drop, Pa	35	60

Fig. 18 Criteria for Louver Sizing

Notes: Based on SMACNA's Duct Construction Standards (2005). No scrap included. Includes reinforcement, and excludes hangers.

Fig. 19 Relative Weight of Rectangular Duct to Round Spiral Duct

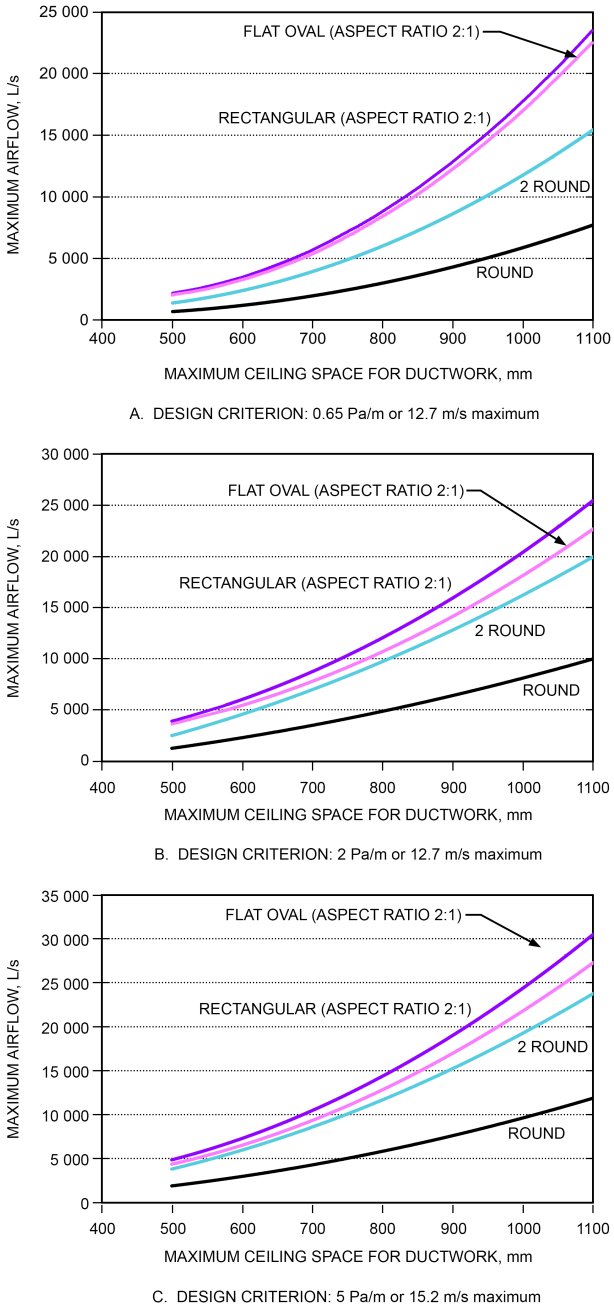


Fig. 20 Maximum Airflow of Round, Flat Oval, and Rectangular Ducts as Function of Available Ceiling Space

Pa/m is at the middle range. In Table 9, six ceiling (plenum) heights ranging from 400 to 1100 mm, in approximately 200 mm increments, are covered. Space allocated for insulation and reinforcement is 50 mm all around. The aspect ratio of the rectangular and flat oval ducts is 2:1. Figure 20 shows the maximum airflow as a function of the design friction rates and plenum spaces, as noted. For example, the 900 mm plenum as a design friction rate of 2 Pa/m is 6360 L/s maximum for a 800 mm round duct; 14 500 L/s for a 1600 × 800 mm rectangular duct; and 21,000 cfm16 300 L/s for a 1600 × 800 mm flat oval duct. The airflow capacity of two round 800 mm ducts is 6360 L/s each.

When selecting a rectangular or flat oval duct, consider the following:

- Rectangular duct has the advantage in **mass** because construction standards for flat oval exist only for +2500 Pa, whereas rectangular has seven pressure classes, starting at 125 Pa. All rectangular pressure classes are ±.

  Note: Negative-pressure flat oval duct systems can be designed by using +2500 Pa sheet gages with the negative-pressure rectangular reinforcement welded to the duct.
- **Low-frequency breakout noise** for flat oval is good, fair for rectangular (Schaffer 2011).
- Duct **rumble** can occur in rectangular duct systems (Paulauskis 2016).
- **Perimeter.** Using rectangular duct instead of flat oval when sized for equivalent diameter increases the perimeter roughly 17 to 7%

Licensed for single user. © 2021 ASHRAE, Inc.

for aspect ratios ranging from 1 to 4, respectively. This increase results in an increased surface area. Flat oval requires less insulation. For a comprehensive study of flat oval and rectangular ducts as they affect system performance, consult McGill (1995).

- **Duct Lengths.** Rectangular duct is available in 1200, 1500, or 1800 mm lengths. Spiral round and flat oval can be provided in longer lengths.

Testing and Balancing

Each air duct system should be tested, adjusted, and balanced. Guidance and procedures are given in Chapter 39 of the 2019 *ASHRAE Handbook—HVAC Applications* and in ASHRAE *Standard* 111. To determine fan total (or static) pressure from field measurements taking into account fan system effect, consult AMCA (2011b) *Publication* 203, which provides numerous fan/system configurations encountered in the field.

Many VAV noise complaints have been traced to control problems. Although most problems are associated with improper installation, many are caused by poor design. The designer should specify high-quality fans or air handlers within their optimum ranges, not at the edge of their operation ranges, where low system tolerances can lead to inaccurate fan flow capacity control. Also, in-duct static pressure sensors should be placed in duct sections having the lowest possible air turbulence (i.e., at least three equivalent duct diameters from any elbow, takeoff, transition, offset, or damper).

6.2 DESIGN RECOMMENDATIONS

- Engage the architect and structural engineer early to coordinate shafts for systems.

Commentary. Consult *Noise and Vibration Control for HVAC Systems* (Schaffer 2011) for the following guidelines related to duct systems:

- Selection of mechanical room walls
- Noise control for mechanical rooms
- Upward noise control for mechanical rooms
- Duct penetrations through walls
- Structural support of rooftop equipment for vibration control

- Route ducts as straight as possible to reduce pressure loss, noise, and first costs.
- Use round spiral ducts whenever round ducts can fit within space constraints.
- Avoid consecutive fittings and close-coupled fittings because they can significantly increase pressure losses.
- Use return air plenums when possible because they reduce both energy and first costs. Plenum return requires fire-rated construction.
- Design air distribution systems to minimize flow resistance and turbulence. High flow resistance increases fan pressure, which results in higher noise being generated by the fan, especially at low frequencies. Turbulence also increases flow noise generated by duct fittings and dampers, especially at low frequencies.
- Efficient fittings create the least turbulence and noise. Figure 21 provides generalized guidelines for minimizing regenerated noise from takeoffs. Tables 10 and 11 provide specific guidance for tees and wyes.
- Duct transitions should not exceed an included angle of 15°.
- To avoid fan system effects, fans should discharge into duct sections that remain straight for as long as possible, up to 10 duct diameters from the fan discharge to allow flow to fully develop (Figure 22). Use the *ASHRAE Duct Fitting Database* (ASHRAE 2016) to account for fan outlet system effects (SD7 and SR7-series).
- Design duct connections at the fan inlet for uniform and straight airflow. Both turbulence and flow separation at the fan blades can significantly increase fan-generated noise. To account for fan inlet system effects, use the *ASHRAE Duct Fitting Database* (ASHRAE 2016) (ED7 and ER7 series).
- For all except very-noise-sensitive applications, select VAV reheat boxes for a total pressure loss from 125 to 150 Pa; for a fan-powered VAV box, from 150 to 175 Pa. For details, see Taylor and Stein (2004).
- VAV terminal unit inlet duct should be the same size as the inlet to the box, unless the box is in the critical path or the length exceeds about 4.5 m from the takeoff. Duct upstream of box inlets should be rigid sheet metal duct, 1.2 m minimum. Do not use flexible duct immediately upstream of VAV boxes.
- See Figure 23 for Schaffer's (2011) guidelines for the installation of single-duct, dual-duct, and induction terminal units, as well as parallel and series flow fan-powered units.
- Place fan-powered mixing boxes away from noise-sensitive areas.
- Use demand-based static pressure set-point reset to reduce fan energy and noise.
- For constant-volume systems, select the fan to operate as near as possible to its rated peak efficiency. Also, select a fan that generates the lowest possible noise at required design conditions. Using an oversized or undersized fan that does not operate at or near rated peak efficiency can substantially increase noise levels. For VAV applications, see Schaffer (2011).

6.3 DESIGN METHODS

Equal Friction Method. The equal friction method for sizing duct systems uses a constant friction rate. The target velocity determines the size of the first duct section both downstream and upstream of the fan. From the size determined by the target velocity, the design friction rate is determined to size all remaining duct sections except for connections to VAV and constant-volume (CV) terminal units and diffusers in the critical path, or for sections whose length exceeds around 4.5 m. In these cases, the inlet to terminal units should have at least three diameters of rigid duct and 2 m maximum of rigid or flexible duct (see Figure 8) to diffusers. The section upstream of the rigid duct to terminal units and the section of rigid/flexible duct to diffusers should be sized by the design friction rate, and an appropriate transition placed between sections. Refer to sections 8 and 9 in Figure 24 for an example.

Static Regain Method. The static regain method uses the conservation of momentum principle, which results in an increase in static pressure when the velocity is reduced in an airstream. This method sizes the main and branch ducts after a junction so that the recovery in static pressure caused by the reduced velocity is approximately equal to the total pressure drop caused by the duct and fittings in the subject duct section according to Equation (41). This is done iteratively by selecting a size for a section and checking to see if the section's static pressure loss is close to zero. The basic steps are to design the first section at the velocity recommended in Table 12. Then each downstream section is subsequently sized using the same duct size as the upstream section as a starting point. If there is no static regain, meaning there is a positive static pressure loss, then the downstream section will be the same size as the upstream section. But, if there is static regain, meaning the change in static pressure is negative, then an opportunity exists to use a smaller duct section. Typically, the next smaller size available that is smaller than the upstream section is selected and the calculations are repeated. Refer to column 12 of Table 13 for examples of static regain.

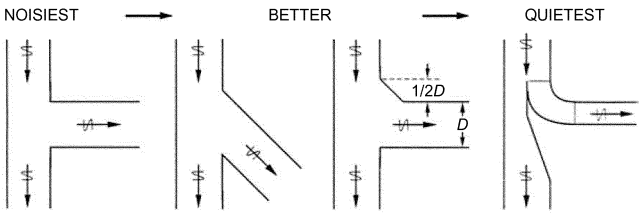

Fig. 21 Guidelines For Minimizing Regenerated Noise in Takeoff
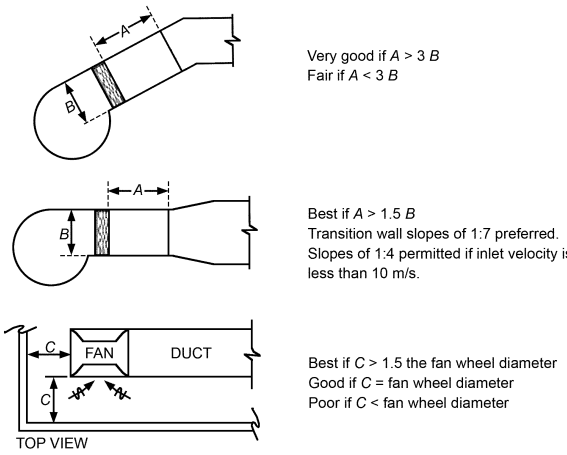
(Schaffer 2011)



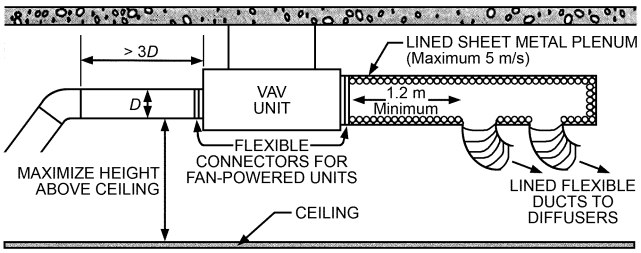


Fig. 22 Guidelines for Centrifugal Fan Installations
(Schaffer 2011)

NOTE: Parallel or side-pocket fan-powered units often require an up- or side-looking lined sheet metal inlet elbow to control fan noise.

Fig. 23 Guidelines for VAV Terminal Unit Installation
(Schaffer 2005)

For connections to VAV and CV terminal units and diffusers in the critical path or the section length with the terminal unit or diffuser exceeds around 4.5 m, the inlet to terminal units should have at least three diameters of rigid duct and 2 m maximum of rigid or flexible duct (see Figure 8) to diffusers. The section upstream of the rigid duct to terminal units and the section of rigid/flexible duct to diffusers should be sized by the static regain method and an appropriate transition placed between sections. Refer to sections 8 and 9 in Figure 24 for an example.

$$p_{v1} = \Delta p_{t,1\text{–}2} + p_{v2} + \Delta p_{s,1\text{–}2} \quad (40)$$

Rearranging,

$$\Delta p_{s,1\text{–}2} = (p_{v1} - p_{v2}) - \Delta p_{t,1\text{–}2} \quad (41)$$

where

p_{v1} = velocity pressure at section 1, Pa
p_{v2} = velocity pressure at section 2, Pa
$\Delta p_{t,1\text{–}2}$ = total pressure loss from section 1 to 2, Pa
$\Delta p_{s,1\text{–}2}$ = static pressure regain (+) or loss (–), Pa

Balancing. When system unbalance is greater than about 30%, it is recommended that balance be improved by changing duct size, and/or fittings from a select few that have comparable efficiency without introducing additional significant turbulence (noise). Tables 10 and 11 are examples.

Noise Control

Understanding what noise is and how to control it is fundamental to duct design. The underlying principles of sound and vibration are covered in Chapter 8. Chapter 49 of the 2019 *ASHRAE Handbook—HVAC Applications* contains technical discussions and design examples helpful to the design engineer. AHRI *Standard* 885 has procedures for estimating sound pressure levels in the occupied zone for the portion of the system downstream of terminal units. For guidance in designing HVAC systems to avoid noise and vibration problems, consult Schaffer (2011). Specifying quiet equipment and designing systems to avoid noise and vibration problems are necessary parts of the design process.

Noise in system comes from fans and generated noise resulting from air turbulence in ducts, individual fittings, close-coupled fittings, dampers, air modulating equipment and diffusers/grilles. Objectionable self-generated duct noise can be controlled by limiting the duct velocity to the values listed in Table 12.

Goals

The goal of duct design is an air distribution system without objectionable noise and minimum life-cycle cost (LCC). Noise can be controlled by limiting the duct velocity to the values listed in Table 12. For example, for ductwork above a suspended acoustical ceiling and with a maximum allowable NC or RC of 35 in the adjoining space, the maximum round and rectangular duct airflow velocities are 15.2 and 8.9 m/s, respectively. Use this velocity to size the first duct section either upstream or downstream from the fan for all duct design methods. Lowering duct velocity reduces system operating cost and minimizes noise from sources other than ducts (fittings, close-coupled fittings, and dampers).

Commentary: In 1988, Dr. Robert J. Tsal developed the T-method (Tsal and Adler 1987; Tsal et al. 1988, 1990) to design systems with a minimum LCC. The T-method was technically sound, but the system cost was not sufficiently accurate. As a result, the T-method was removed from the Handbook in 2013.

Design Method to Use

Supply Duct Sizing.

- Size fan supply ducts by either the equal friction (EF) or static regain (SR) method. The duct velocity anywhere in the system should not exceed the velocity listed in Table 12.
- Size ducts downstream of terminal boxes, toilet exhaust ducts, and other low-pressure systems (e.g., in Figure 25C) using the equal friction method with a friction rate in the range from 160 Pa per metre such that the duct velocity in the duct anywhere in the system does not exceed the values in Table 12. Use Table 14 as a guide to select the design friction rate.
- Terminal unit (VAV box) runouts should be full size with the exception that runouts in the "critical" path or a runout length greater than about 4.5 m should be a minimum 1.5 m of rigid duct full size and the remainder's size determined by the design method (e.g., Example 8 and Figure 24).
- Diffuser runouts should be full size, except for runouts in the critical path or a runout length greater than about 4.5 m: these runouts

*Table developed using *ASHRAE Duct Fitting Database* (ASHRAE 2016): CD11-4 (ε = 0.12 mm; ρ = 1.204 kg/m³).

should be at least 2 m of flexible-duct full size, and the remainder's size determined by the design method.

Return Duct Systems.

- Sizing ducted returns depend on economizer relief system. For systems with return fans (Figure 25A), the return air ducts are sized using the EF method. The SR method does not work for negative-pressure duct systems.

  If building relief is by relief fans or gravity/motorized dampers, pressure drop should be kept low as shown by the total pressure grade line associated with Figures 25B and 25C.

  Control dampers in the economizer system should be selected (parallel or opposed blade) and sized in compliance with ASHRAE *Guideline* 16. Louvers should be sized in accordance with the section on Louvers, under Duct Design.
- Unducted return air shafts are typically sized for low pressure loss using either a fixed friction rate, velocity, or both. Typically, shafts are simply sized based on velocity. Maximum velocities are generally in the 4.1 to 6.1 m/s range through the free area at the top of the shaft (highest airflow rate).
- Diffuser/grille runouts should be designed by the design method of choice and a transition located at the outlet. For outlets in the critical path, the outlet duct size should be increased. Registers should not be used because of the damper.

Example 8. For the VAV system shown in Figure 25, design the duct system by both the equal friction (EF) and static regain (SR) methods, and compare the section duct sizes, total pressure required for each path, and the unbalance between paths.

The system is located in Denver (1655 m elevation) and the duct is spiral round, galvanized steel (absolute roughness ε = 0.12 mm). The duct system is located above a suspended acoustical ceiling, and the allowable background sound in the occupied spaces is NC-35. Terminals T1, T2, T3, and T4 (VAV boxes with a one-row hot-water coil) are 380 L/s. VAV box loss coefficients are 1.67.

Solution: Use the *ASHRAE Duct Fitting Database* (ASHRAE 2016) to determine the air density, which is used to identify the velocity pressure and fitting loss coefficients for fittings. Density is 0.978 kg/m³ (Figure 26). The maximum design duct velocity from Table 12 is 15.2 m/s. The EF and SR calculations are shown by Tables 13 and 15.

For both the EF and SR designs, the duct size for Section 2 is 375 mm determined using CD11-3 (Figure 27). Sizing the remaining section depends on the design method. For the equal friction design method, the system equal friction (also from CD11-3) is 4.2 Pa/m. Knowing the system design friction rate, the duct sizes are determined by CD11-4. Figure 28 is an example for Section 4. For the static regain method, all sections other than the terminal unit runouts are sized by iterating using Equation (41) (column 12 in Table 13). For example, the results of the iteration for Section 4 are summarized by Table 16. The solution is the diameter that gives the result from Equation (41) that is closest to zero: in this case, 350 mm

Tables 17 and 18 summarize the results. The SR design is slightly better balanced, 19% compared to 23%, and the SR design requires 9% less energy. In addition, the SR sizes are slightly larger, and thus potentially less noisy. Both methods have static regain, but the SR design uses the regain more efficiently.

6.4 INDUSTRIAL EXHAUST SYSTEMS

Chapter 33 of the 2019 *ASHRAE Handbook—HVAC Applications* discusses design criteria, including hood design, for industrial exhaust systems. Exhaust systems conveying vapors, gases, and smoke are designed by the equal-friction method. Systems conveying particulates are designed by the constant velocity method at duct velocities adequate to convey particles to the system air cleaner. For contaminant transport velocities, see Table 2 in Chapter 33 of the 2019 *ASHRAE Handbook—HVAC Applications*. 350 mm

Two pressure-balancing methods can be considered when designing industrial exhaust systems. One method uses balancing devices (e.g., dampers, blast gates) to obtain design airflow through each hood. The other approach balances systems by adding resistance to ductwork sections (i.e., changing duct size, selecting different fittings, increasing airflow). This self-balancing method is preferred, especially for systems conveying abrasive materials. Where potentially explosive or radioactive materials are conveyed, the prebalanced system is mandatory because contaminants could accumulate at the balancing devices. To balance systems by increasing airflow, use Equation (42), which assumes that all ductwork has the same diameter and that fitting loss coefficients, including main and branch tee coefficients, are constant.

$$Q_c = Q_d(P_h/P_l)^{0.5} \quad (42)$$

where

Q_c = airflow rate required to increase P_l to P_h, L/s
Q_d = total airflow rate through low-resistance duct run, L/s
P_h = absolute value of pressure loss in high-resistance ductwork section(s), Pa

Licensed for single user. © 2021 ASHRAE, Inc.

P_l = absolute value of pressure loss in low-resistance ductwork section(s), Pa

For systems conveying particulates, use elbows with a large centerline radius-to-diameter ratio (r/D), greater than 1.5 whenever possible. If r/D is 1.5 or less, abrasion in dust-handling systems can reduce the life of elbows. Elbows are often made of seven or more gores, especially in large diameters. For converging flow fittings, a 30° entry angle is recommended to minimize energy losses and abrasion in dust-handling systems. For the entry loss coefficients of hoods and equipment for specific operations, see Chapter 33 of the 2019 *ASHRAE Handbook—HVAC Applications* and ACGIH (2016).

Commentary: Fitting CD11-5 of the *ASHRAE Duct Fitting Database* (ASHRAE 2016) is available for sizing minimum-velocity ducts conveying particulates.

Example 9. For the metalworking exhaust system in Figures 29 and 30, size the ductwork and calculate fan static pressure requirement for an industrial exhaust designed to convey granular materials. Pressure-

Fig. 28 EF Design: Sizing Sections 4, 6, and 8 Knowing Design Friction Rate (Section 4 Shown)

balance the system by changing duct sizes and adjusting airflow rates. Minimum particulate transport velocity for the chipping and grinding table ducts (sections 1 and 5, Figure 30) is 20 m/s. For ducts associated with the grinder wheels (sections 2, 3, 4, and 5), minimum duct velocity is 23 m/s. Ductwork is galvanized steel, with absolute roughness of 0.09 mm. Use sizes for which spiral duct is available (80, 100, 125, 140, 150, 160, 180, 200, 224, 250, 280, 300, 315, 355, 400, 450, 500, 560, 600, 630, 710, 800, 900, 1000, 1120, 1250, 1300, 1400, 1500, 1600, 1800, 2000, 2100, 2200, 2300, 2400, and 2500 mm).

The building is one story, and the design wind velocity is 9 m/s. For the stack, use design J shown in Figure 2 in Chapter 46 of the 2019 *ASHRAE Handbook—HVAC Applications* for complete rain protection; stack height, determined by calculations from Chapter 46, is 4.9 m above the roof. This height is based on minimized stack downwash; therefore, the stack discharge velocity must exceed 1.5 times the design wind velocity.

Solution: The following table summarizes initial duct sizes and transport velocities for contaminated ducts upstream of the collector. The 22.8 m/s velocity in sections 2 and 3 is acceptable because the transport velocity is not significantly lower than 23 m/s. For the next available duct size (160 mm diameter), the duct velocity is 28.8 m/s, significantly higher than 23 m/s.

Design calculations up through the junction after sections 1 and 4 are summarized as follows:

For (initial) design 1, the imbalance between section 1 and section 2 (or 3) is 383 Pa, with section 1 requiring additional resistance. Decreasing section 1 duct diameter by manufactured spiral duct sizes results in the least imbalance, 88 Pa, when the duct diameter is 200 mm (design 2). Because section 1 requires additional resistance, estimate the new airflow rate using Equation (42):

$$Q_{c,1} = 850(850/762)^{0.5} = 900 \text{ L/s}$$

At 900 L/s flow in section 1, 130 Pa imbalance remains at the junction of sections 1 and 4. By trial-and-error solution, balance is attained when the flow in section 1 is 860 L/s. The duct between the collector and fan inlet is 355 mm round to match the fan inlet (340 mm diameter). To minimize downwash, the stack discharge velocity must exceed 13.5 m/s, 1.5 times the design wind velocity (9 m/s) as stated in the problem definition. Therefore, the stack is 355 mm round, and the stack discharge velocity is 14.5 m/s.

Table 19 summarizes the system losses by sections. The straight duct friction factor and pressure loss were calculated by Equations (18) and (19). Table 20 lists fitting loss coefficients and input parameters necessary to determine the loss coefficients. The fitting loss coefficients are from the *ASHRAE Duct Fitting Database*. Figure 31 shows a pressure grade line of the system. Fan total pressure, calculated by Equation (15), is 1992 Pa. To calculate the fan static pressure, use Equation (17):

$$P_s = 1992 - 192 = 1800 \text{ Pa}$$

where 192 Pa is the fan outlet velocity pressure. The fan airflow rate is 1440 L/s, and its outlet area is 0.081 m^3 (260 by 310 mm). Therefore, the fan outlet velocity is 17.9 m/s.

Hood suction for the chipping and grinding table hood is 560 Pa, calculated by Equation (5) from Chapter 33 of the 2019 *ASHRAE Handbook—HVAC Applications* [$P_{s,h} = (1 + 0.25)(451) = 560$ Pa, where 0.25 is hood entry loss coefficient C_o, and 451 is duct velocity pressure P_v a few diameters downstream from the hood]. Similarly, hood suction for each grinder wheel is 170 Pa

THIS CHAPTER discusses pipe systems, materials, design, installation, supports, stress calculations, pipe expansion and flexibility, bends and loops, and application of pipe systems commonly used for heating, air conditioning, refrigeration, and service water. When selecting and applying components; applicable local codes, state or provincial codes, and voluntary industry standards (some of which have been adopted by code jurisdictions) must be followed. Further details on specific piping systems can be found in application-specific chapters of the ASHRAE Handbook.

1. FUNDAMENTALS

1.1 CODES AND STANDARDS

The following organizations in the United States issue codes and standards for piping systems and components:

ASME	American Society of Mechanical Engineers
ASTM	American Society for Testing and Materials
NFPA	National Fire Protection Association
ICC	International Code Council
MSS	Manufacturers Standardization Society of the Valve and Fittings Industry, Inc.
AWWA	American Water Works Association

Parallel federal specifications also have been developed by government agencies and are used for many public works projects. Chapter IV of ASME *Standard* B31.9 lists applicable U.S. codes and standards for HVAC piping. In addition, it gives requirements for safe design and construction of piping systems for building heating and air conditioning. ASME *Standard* B31.5 gives similar requirements for refrigerant piping.

1.2 DESIGN CONSIDERATIONS

Pipes are conduits in which fluids [compressible (e.g., air, steam) and noncompressible (e.g., water)] flow in a system, in response to a pressure differential. Piping system designers should assess the following aspects:

- Code requirements.
- Load: the amount of energy or fluid to be moved through the pipe to where it is needed; determination of load is not covered in this chapter (see Chapters 16 to 18 for information on load calculations).
- Working fluid and fluid properties in the pipe.
- Pressure and temperature of the fluid.
- External environment of the pipe: outdoor installations deal with temperature extremes, environmental contaminants, and ultraviolet radiation. Other environments could contain caustic chemicals. Soil can contain elements that can be corrosive to underground pipe systems.
- Installation cost.
- Pipe's resistance to chemical attack from the fluid.

When designing a fluid flow system, two related but distinct concerns emerge: sizing the pipe and determining the flow/pressure relationship. The two are often confused because they can use the same equations and design tools. Nevertheless, they should be determined separately.

This chapter focuses on sizing the pipe during the design phase, and to this end presents design charts and tables for specific fluids in addition to the equations that describe fluid flow in pipes. Once a system has been sized, it should be analyzed with more detailed methods of calculation to determine the pump pressure, if applicable, required to achieve the desired flow. Computerized methods are well suited to handling the details of calculating losses around an extensive system.

Not discussed in detail in this chapter, but of potentially great importance, are physical and chemical considerations such as pipe and fitting design; materials; and joining methods appropriate for working pressures and temperatures encountered, as well as resistance to chemical attack by the fluid. For more information, see Eshbach (2009), Heald (2002), and Nayyar (1999).

For fluids not included in this chapter or for piping materials of different dimensions, manufacturers' literature frequently supplies pressure drop charts. The Darcy-Weisbach equation, with the Moody chart or Colebrook equation, can be used as an alternative to pressure drop charts or tables.

1.3 GENERAL PIPE SYSTEMS

Metallic Pipe Systems

Each HVAC system and, under some conditions, portions of a system require a study of the conditions of operation to determine suitable materials. For example, because the static pressure of water in a high-rise building is higher in the lower levels than in the upper levels, a heavier pipe or different materials may be required for different vertical zones.

Table 1 lists some typical systems and materials used for heating and air-conditioning metallic piping. The list is not all inclusive, because piping systems are constantly being developed. The pressure and temperature rating of each component selected must be

The preparation of this chapter is assigned to TC 6.1, Hydronic and Steam Equipment and Systems.

[a]Maximum allowable working pressures have been derated in this table. Higher system pressures can be used for lower temperatures and smaller pipe sizes. Pipe, fittings, joints, and valves must all be considered.

[b]Temperature and pressure relationships can vary based on pipe material composition, size, class, and schedule.

[c]Lead- and antimony-based solders are prohibited for potable water systems. Brazing should be used.

[d]Piping codes typically require thicker-walled pipe for threaded joints to maintain corrosion allowance and pressure ratings.

[e]All plumbing codes require both hot and cold water piping to have a 689 kPa at 82°C rating.

[f]Threads are not recommended on Schedule 40 plastic pipe.

[g]Designer should confirm that all materials are suitably rated for intended operation.

[a]Before selecting material, check availability of suitable range of sizes and fittings and of satisfactory joining method. Also have manufacturer verify the best material for purpose intended.
[b]Consult local building codes for compliance of materials listed.

considered; the lowest rating establishes the operating limits of the system.

Nonmetallic (Plastic) Pipe Systems

Nonmetallic pipe is used in HVAC and plumbing. Plastic is light, generally inexpensive, and corrosion resistant. Plastic also has a low "C" factor (i.e., its surface is very smooth), resulting in lower pumping power requirements and smaller pipe sizes. Plastic pipe's disadvantages include rapid loss of strength at temperatures above ambient and a high coefficient of linear expansion. The modulus of elasticity of plastics is low, resulting in a short support span. Some jurisdictions do not allow certain plastics in buildings because of toxic products emitted during fires. Plenum-rated plastic and insulation may be used to achieve a plenum rating; check with the authority having jurisdiction (AHJ).

Table 2 lists nonmetallic materials used for service water and heating and air-conditioning piping. The pressure and temperature rating of each component selected must be considered; the lowest rating establishes the operating limits of the system.

Special Systems

Some piping systems are governed by separate codes or standards. Generally, any failure of the piping in these systems is dangerous to the public, so some local areas have adopted laws enforcing the codes, such as the following:

- **Boiler piping:** ASME *Standard* B31.1 and the ASME *Boiler and Pressure Vessel Code* (Section I) specify piping inside code-required stop valves on boilers that operate above 100 kPa (gage) with steam, or above 1.1 MPa or 120°C with water. These codes require fabricators and contractors to be certified for such work. The field or shop work must also be inspected while it is in progress, by inspectors commissioned by the National Board of Boiler and Pressure Vessel Inspectors.
- **Refrigeration piping:** ASHRAE *Standard* 15 and ASME *Standard* B31.5.
- **Plumbing systems:** Local codes.
- **Sprinkler systems:** NFPA *Standard* 13.
- **Fuel gas:** NFPA *Standard* 54/ANSI *Standard* Z223.1.

1.4 DESIGN EQUATIONS

Darcy-Weisbach Equation

Pressure drop caused by fluid friction in fully developed flows of all well-behaved (Newtonian) fluids is described by the Darcy-Weisbach equation:

$$\Delta p = f\left(\frac{L}{D}\right)\left(\frac{\rho V^2}{2}\right) \quad (1)$$

where

Δp = pressure drop, Pa
f = friction factor, dimensionless (from Moody chart, Figure 13 in Chapter 3)
L = length of pipe, m
D = internal diameter of pipe, m
ρ = fluid density at mean temperature, kg/m^3
V = average velocity, m/s

This equation is often presented in specific energy form as

$$\Delta h = \frac{\Delta p}{\rho g} = f\left(\frac{L}{D}\right)\left(\frac{V^2}{2g}\right) \quad (2)$$

where

Δh = energy loss, m
g = acceleration of gravity, m/s^2

In this form, the fluid's density does not appear explicitly (although it is in the Reynolds number that influences f).

The friction factor f is a function of pipe roughness ε, inside diameter D, and parameter Re, the Reynolds number:

$$\mathrm{Re} = DV\varepsilon/\mu \quad (3)$$

where

Re = Reynolds number, dimensionless
ε = absolute roughness of pipe wall, m
μ = dynamic viscosity of fluid, Pa·s

The friction factor is frequently presented on a Moody chart (Figure 13 in Chapter 3) giving f as a function of Re with ε/D as a parameter.

A useful fit of smooth and rough pipe data for the usual turbulent flow regime is the **Colebrook** equation:

$$\frac{1}{\sqrt{f}} = 1.74 - 2\log\left(\frac{2\varepsilon}{D} + \frac{18.7}{\mathrm{Re}\sqrt{f}}\right) \quad (4)$$

Another form of Equation (4) appears in Chapter 21, but the two are equivalent. Equation (4) is useful in showing behavior at limiting cases: as ε/D approaches 0 (smooth limit), the $18.7/\mathrm{Re}\sqrt{f}$ term dominates; at high ε/D and Re (fully rough limit), the $2\varepsilon/D$ term

Equation (4) is implicit in f; that is, f appears on both sides, so a value for f is usually obtained iteratively.

Hazen-Williams Equation

A less widely used alternative to the Darcy-Weisbach formulation for calculating pressure drop is the Hazen-Williams equation, which is expressed as

$$\Delta p = 6.819L\left(\frac{V}{C}\right)^{1.852}\left(\frac{1}{D}\right)^{1.167}(\rho g) \tag{5}$$

or

$$\Delta h = 6.819L\left(\frac{V}{C}\right)^{1.852}\left(\frac{1}{D}\right)^{1.167} \tag{6}$$

where C = roughness factor.

Typical values of C are 150 for plastic pipe and copper tubing, 140 for new steel pipe, down to 100 and below for badly corroded or very rough pipe.

Valve and Fitting Losses

Valves and fittings cause pressure losses greater than those caused by the pipe alone. One formulation expresses losses as

$$\Delta p = K\rho\left(\frac{V^2}{2}\right) \text{ or } \Delta h = K\left(\frac{V^2}{2g}\right) \tag{7}$$

where K = geometry- and size-dependent loss coefficient (Tables 3 to 6)and ρ = density of fluid ≈ 1000 kg/m^3 for water at temperatures below 120°C.

Example 1. Determine the pressure drop for 15°C water flowing at 1 m/s through a nominal 25 mm, 90° threaded elbow.

Solution: Use Equation (7). From Table 3, the K for a 25 mm, 90° threaded elbow is 1.5.

$$\Delta p = 1.5 \times 1000 \times 1^2/2 = 750 \text{ Pa}$$

The loss coefficient for valves appears in another form as A_v, a dimensional coefficient expressing the flow through a valve at a specified pressure drop.

$$Q = A_v\sqrt{\Delta p} \tag{8}$$

where

Q = volumetric flow, m^3/s
A_v = valve coefficient, m^3/s at Δp = 1 Pa
Δp = pressure drop, Pa

See the section on Control Valve Sizing in Chapter 46 of the 2020 *ASHRAE Handbook—HVAC Systems and Equipment* for more information on valve coefficients.

Example 2. Determine the volumetric flow through a valve with A_v = 0.00024 for an allowable pressure drop of 35 kPa.

Solution: Use Equation (8).

$$Q = 0.00024\sqrt{35\ 000/1000} = 0.0014 \text{ m}^3/\text{s} = 1.4 \text{ L/s}$$

Alternative formulations express fitting losses in terms of equivalent lengths of straight pipe (see Tables 8 and 27). Pressure loss data for fittings are also presented in Idelchik (1986).

Equation (7) and data in Tables 3 and 4 are based on the assumption that separated flow in the fitting causes the K factors to be independent of Reynolds number. In reality, the K factor for most pipe fittings

varies with Reynolds number. Tests by Rahmeyer (1999a, 1999b, 2002a, 2002b) (ASHRAE research projects RP-968 and RP-1034) on 50 mm threaded and 100, 300, 400, 500, and 600 mm welded steel fittings demonstrate the variation and are shown in Tables 6 and 7. The studies also present *K* factors of diverting and mixing flows in tees, ranging from full through flow to full branch flow. They also examined the variation in *K* factors caused by variations in geometry among manufacturers and by surface defects in individual fittings.

Hegberg (1995) and Rahmeyer (1999a, 1999b) discuss the origins of some of the data shown in Tables 6 and 7. The Hydraulic Institute (1990) data appear to have come from Freeman (1941), work that was actually performed in 1895. The work of Giesecke (1926) and Giesecke and Badgett (1931, 1932a, 1932b) may not be representative of present-day fittings.

Further extending the work on determination of fitting *K* factors to PVC piping systems, Rahmeyer (2003a, 2003b) (ASHRAE research project RP-1193) found the data in Tables 8 and 9 giving *K* factors for Schedule 80 PVC 50, 100, 150, and 200 mm ells, reducers, expansions, and tees. The results of these tests are also presented in the cited papers in terms of equivalent lengths. In general, PVC fitting geometry varied much more from one manufacturer to another than steel fittings did.

Bushing type		0.94 to 0.95	9.9 to 10.0
Gradual reducer type		0.99	10.4

Losses in Multiple Fittings

Typical fitting loss calculations are done as if each fitting is isolated and has no interaction with any other. Rahmeyer (2002c) (ASHRAE research project RP-1035) tested 50 mm threaded ells and 100 mm ells in two and three fitting assemblies of several geometries, at varying spacing. Figure 1 shows the geometries, and Figures 2 and 3 show the ratio of coupled *K* values to uncoupled *K* values (i.e., fitting losses for the assembly compared with the sum of losses from the same number of isolated fittings).

The most important conclusion is that the interaction between fittings always reduces the loss. Also, although geometry of the assembly has a definite effect, the effects are not the same for 50 mm threaded and 100 mm welded ells. Thus, the traditional practice of adding together losses from individual fittings gives a conservative (high-limit) estimate.

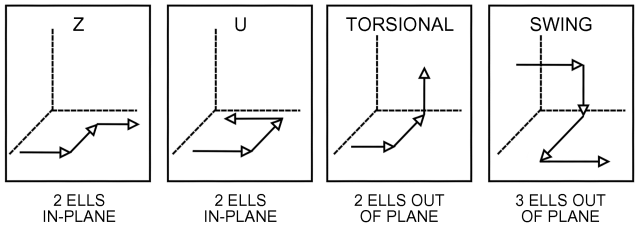

Fig. 1 Close-Coupled Test Configurations

Calculating Pressure Losses

The most common engineering design flow loss calculation selects a pipe size for the desired total flow rate and available or allowable pressure drop.

Because either formulation of fitting losses requires a known diameter, pipe size must be selected before calculating the detailed influence of fittings. A frequently used rule of thumb assumes that the design length of pipe is 50 to 100% longer than actual to account for fitting losses. After a pipe diameter has been selected on this basis, the influence of each fitting can be evaluated.

Stress Calculations

Metallic Pipe. Although stress calculations are seldom required, the factors involved should be understood. The main areas of concern are (1) internal pressure stress, (2) longitudinal stress caused by pressure and mass, and (3) stress from expansion and contraction.

ASME *Standard* B31 standards establish a basic allowable stress *S* equal to one-fourth of the minimum tensile strength of the material. This value is adjusted, as discussed in this section, because of the nature of certain stresses and manufacturing processes.

Licensed for single user. © 2021 ASHRAE, Inc.

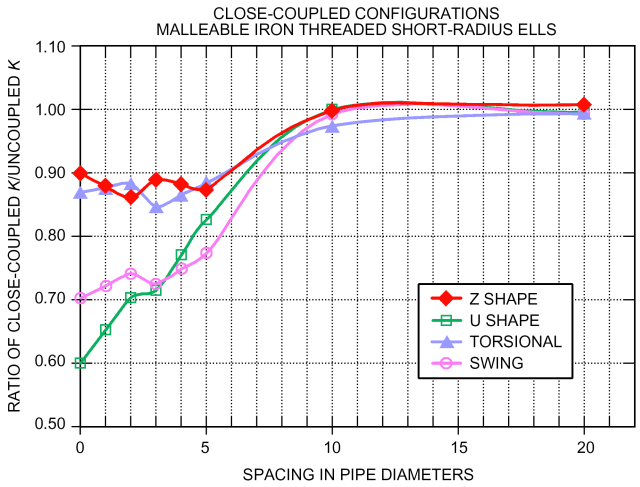

Fig. 2 Summary Plot of Effect of Close-Coupled Configurations for 50 mm Ells

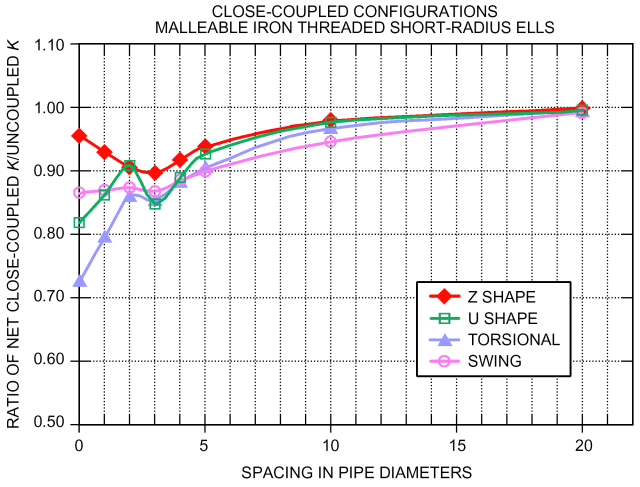

Fig. 3 Summary Plot of Effect of Close-Coupled Configurations for 100 mm Ells

Hoop stress caused by internal pressure is the major stress on pipes. Because some forming methods form a seam that may be weaker than the base material, ASME *Standard* B31.9 specifies a joint efficiency factor E, multiplied by the basic allowable stress to establish a maximum allowable stress value in tension S_E. (Table A-1 in ASME *Standard* B31.9 lists values of S_E for commonly used pipe materials.) The joint efficiency factor can be significant; for example, seamless pipe has a joint efficiency factor of 1, so it can be used to the full allowable stress (one-quarter of the tensile strength). In contrast, butt-welded pipe has a joint efficiency factor of 0.60, so its maximum allowable stress must be derated ($S_E = 0.6S$).

Equation (9) determines the minimum wall thickness for a given pressure. Equation (10) determines the maximum pressure allowed for a given wall thickness.

$$t_m = \frac{pD}{2S_E} + A \tag{9}$$

$$p = \frac{2S_E(t_m - A)}{D} \tag{10}$$

Table 9 Test Summary for Loss Coefficients K of PVC Tees

Branching		
Schedule 80 PVC Fitting	**$K_{1\text{-}2}$**	**$K_{1\text{-}3}$**
50 mm injection molded branching tee, 100% line flow	0.13 to 0.26	—
50/50 flow	0 to 0.12	0.74 to 1.02
100% branch flow	—	0.98 to 1.39

50/50 flow	1.19 to 1.88	0.98 to 1.88
100% mix flow	—	0.88 to 1.02
150 mm injection molded mixing tee, 100% line flow	0.06 to 0.14	—
50/50 flow	1.26 to 1.80	1.02 to 1.60
100% mix flow	—	0.90 to 1.07
150 mm fabricated mixing tee, 100% line flow	0.19 to 0.21	—
50/50 flow	2.94 to 3.32	2.57 to 3.17
100% mix flow	—	1.72 to 1.98
200 mm injection molded mixing tee, 100% line flow	0.04 to 0.09	—
50/50 flow	1.10 to 1.60	0.96 to 1.32
100% mix flow	—	0.81 to 0.93
200 mm fabricated mixing tee, 100% line flow	0.13 to 0.70	—
50/50 flow	2.36 to 10.62	2.02 to 2.67
100% mix flow	—	1.34 to 1.53

Coefficients based on average velocity of 2.43 m/s. Range of values varies with fitting manufacturers. Line or straight flow is $Q_2/Q_1 = 100\%$. Branch flow is $Q_2/Q_1 = 0\%$.

where

S_A = allowable stress range, kPa
S_c = allowable cold stress at coolest temperature system will experience, kPa
S_h = allowable hot stress at hottest temperature system will experience, kPa

Both equations incorporate an allowance factor A to compensate for manufacturing tolerances, material removed in threading or grooving, and corrosion. For the seamless, butt-welded, and electric resistance welded (ERW) pipe most commonly used in HVAC work, the standards apply a manufacturing tolerance of 12.5%. Working pressure for steel pipe (see Table 16) has been calculated using a manufacturing tolerance of 12.5%, standard allowance for depth of thread (where applicable), and a corrosion allowance of 1.65 mm for pipes 65 mm and larger and 0.64 mm for pipes 50 mm

Licensed for single user. © 2021 ASHRAE, Inc.

and smaller. Where corrosion is known to be greater or smaller, pressure rating can be recalculated using Equation (10). Higher pressure ratings than shown in Table 16 can be obtained (1) by using ERW or seamless pipe in lieu of continuous-weld (CW) pipe 100 mm and less, and seamless pipe in lieu of ERW pipe 125 mm and greater (because of higher joint efficiency factors); or (2) by using heavier-wall pipe.

Longitudinal stresses caused by pressure, mass, and other sustained forces are additive, and the sum of all such stresses must not exceed the basic allowable stress S at the highest temperature at which the system will operate. Longitudinal stress caused by pressure equals approximately one-half the hoop stress caused by internal pressure; thus, at least one-half the basic allowable stress is available for mass and other sustained forces. This factor is taken into account in Table 11.

Stresses caused by expansion and contraction are cyclical, and, because creep allows some stress relaxation, the ASME *Standard* B31 series allows designing to an allowable stress range S_A as calculated by Equation (11). Table 15 lists allowable stress ranges for commonly used piping materials.

$$S_A = 1.25S_c + 0.25S_h \tag{11}$$

where

S_A = allowable stress range, kPa
S_c = allowable cold stress at coolest temperature system will experience, kPa
S_h = allowable hot stress at hottest temperature system will experience, kPa

Nonmetallic. Both thermoplastics and thermosets have an allowable stress derived from a **hydrostatic design basis stress (HDBS)**. The HDBS is determined by a statistical analysis of both static and cyclic stress rupture test data as set forth in ASTM *Standard* D2837 for thermoplastics and ASTM *Standard* D2992 for glass-fiber-reinforced thermosetting resins.

The allowable stress, called the **hydrostatic design stress (HDS)**, is obtained by multiplying the HDBS by a service factor. HDS values recommended by some manufacturers and those allowed by ASME *Standard* B31 are listed in Table 18.

The pressure design thickness for plastic pipe can be calculated using the code stress values and the formula in Equation (12):

$$t = pD/(2S + p) \tag{12}$$

where

t = pressure design thickness, mm
p = internal design pressure, kPa (gage)
D = pipe outside diameter, mm
S = hydrostatic design stress (HDS), kPa

The minimum required wall thickness can be found by adding an allowance for mechanical strength, threading, grooving, erosion, and corrosion to the calculated pressure design thickness.

Another method of rating pressure rating of piping used by manufacturers is the **standard dimension ratio (SDR)**, which is the ratio of the pipe diameter to the wall thickness:

$$\text{SDR} = D/s \tag{13}$$

where

D = pipe outside diameter, mm
s = pipe wall thickness, mm

An SDR of 11 means that the outside diameter D of the pipe is 11 times the thickness of the wall s. A high SDR means that the pipe's wall is thin compared to its diameter, and a low SDR means that the pipe's wall is thick relative to pipe diameter. SDR is inversely correlated with pressure rating: high SDR indicates a low pressure rating, whereas low-SDR pipes have higher pressure ratings.

There are many formulations of the polymers used for piping materials, and different joining methods for each, so manufacturers' recommendations should be followed. Most catalogs give pressure ratings for pipe and fittings at various temperatures up to the maximum the material will withstand.

1.5 SIZING PROCEDURE

A procedure for sizing piping systems is as follows:

1. Determine system type (open, closed, compressible, incompressible, pumped, gravity feed, domestic, etc.).
2. Determine type and properties of fluid to be conveyed in the pipe.
3. Determine temperatures used (high, low) and temperature differentials.
4. Identify system pressures encountered in the system (working, maximum, low, fill, and relief pressures).
5. Determine load at each device (e.g., heating or cooling requirements, fixture units for plumbing) to find flow.
6. Sketch main, risers, and branches, and indicate equipment to be served and each device's flow rate.
7. Determine flow of supply pipe for each pipe segment run by summing the loads at the furthest device and running back to the source.
8. Determine flow of each return pipe by starting at the first device returning water and summing the loads back to the source (when applicable).
9. Determine equivalent length of pipe in the main lines, risers, branches, and returns. Because pipe sizes are not known, the exact equivalent length of various fittings cannot be determined. Add the equivalent lengths, starting at the beginning and proceeding along the mains, risers, branches, and returns (when applicable).
10. **In domestic or gravity feed:** calculate the approximate design value of the average pressure drop per metre length of pipe in equivalent length determined in step 9. **In pumped system:** calculate pressure drop H using the flow rate and pressure drop for pipe from Equations (2) or (6), the valves and fittings using head drop from Equation (7), and head from the devices from the manufacturer's data.

$$\Delta p = (p_s - 9.8H - p_f - p_m)/L \tag{14}$$

where

Δp = average pressure loss per metre of equivalent length of pipe, kPa
p_s = pressure at the source, kPa
p_f = minimum pressure required to operate device, kPa
p_m = pressure drop through any meters, kPa
H = height of highest fixture above source (if open system), m
L = equivalent length determined in step 4, m

11. **In domestic or gravity system:** from the expected rate of flow (step 5) and Δp (step 10), select pipe sizes. **In pumped system:** select the pump using the flow rate and calculated H.

1.6 PIPE-SUPPORTING ELEMENTS

Pipe-supporting elements consist of (1) hangers, which support from above; (2) supports, which bear load from below; and (3) restraints, such as anchors and guides, that limit or direct movement as well as support loads. Pipe-supporting elements must withstand all static and dynamic conditions, including the following:

- Mass of pipe, valves, fittings, insulation, and fluid contents, including test fluid if using heavier-than-normal media
- Occasional loads such as ice, wind, and seismic forces or testing loads (e.g., hydrostatic loads on a steam pipe)

Licensed for single user. © 2021 ASHRAE, Inc.

Table 10 Capacities of ASTM A36 Steel Threaded Rods

Rod Diameter, mm	Root Area of Coarse Thread, mm^2	Maximum Load,* N
6.4	17.4	1 070
10	43.9	2 720
13	81.3	5 030
16	130.3	8 060
19	194.8	12 100
22	270.3	16 800
25	356.1	22 100
32	573.5	35 600

*Based on allowable stress of 83 MPa reduced by 25% using root area in accordance with ASME *Standard* B31.1 and MSS *Standard* SP-58.

- Forces imposed by thermal expansion and contraction of pipe bends and loops
- Frictional, spring, and pressure thrust forces imposed by expansion joints in the system
- Frictional forces of guides and supports
- Other loads (e.g., water hammer, vibration, reactive force of relief valves)
- Test load and force

In addition, pipe-supporting elements must be evaluated in terms of stress at the points of connection to the pipe and the building. Stress at the point of connection to the pipe is especially important for base elbow and trunnion supports, because this stress is usually the limiting parameter, not the strength of the structural member. Loads on anchors, cast-in-place inserts, and other attachments to concrete should not be more than one-fifth the ultimate strength of the attachment, as determined by manufacturers' tests. All loads on the structure should be communicated to and coordinated with the structural engineer.

The ASME B31 standards establish criteria for the design of pipe-supporting elements, and the Manufacturers Standardization Society of the Valve and Fittings Industry (MSS) has established standards for the design, fabrication, selection, and installation of pipe hangers and supports based on these codes.

MSS *Standard* SP-69 and the catalogs of many manufacturers illustrate the various hangers and components and provide information on the types to use with different pipe systems. Table 10 lists maximum safe loads for threaded steel rods, and Tables 11 and 12 show suggested pipe support spacing for metal and PVC pipes, respectively.

Loads on most pipe-supporting elements are moderate and can be selected safely in accordance with manufacturers' catalog data and the information presented in this section; however, some loads and forces can be very high, especially in multistory buildings and for large-diameter pipe, particularly where expansion joints are used at a high operating pressure. Consequently, a qualified engineer should design or review all anchors and pipe-supporting elements, especially for the following:

- Steam systems operating above 100 kPa (gage)
- Hydronic systems operating above 1.1 MPa or 120°C
- Risers over 10 stories or 30 m
- Systems with expansion joints, especially for pipe diameters 80 mm and greater
- Pipe sizes over 300 mm diameter
- Anchor loads greater than 44 kN
- Moments on pipe or structure in excess of 1.4 kN·m

Hanger Spacing and Pipe Wall Thickness

Table 11 suggests minimum pipe hanger spacing for use unless exceeded by the local authority having jurisdiction or engineering calculations. The primary factors determining pipe wall thickness are hoop stress caused by internal pressure, and longitudinal stresses caused by pressure, mass, and other sustained loads. Detailed stress calculations are seldom required for HVAC applications because standard pipe has ample thickness to sustain the pressure and longitudinal stress caused by mass (assuming hangers are spaced in accordance with Table 11).

Table 11 Suggested Hanger Spacing and Rod Size for Straight Horizontal Runs

Nominal O.D., mm	Hanger Spacing, m			Rod Size, mm
	Standard Steel Pipe*		Copper Tube	
	Water	Steam	Water	
15	2.1	2.4	1.5	6.4
20	2.1	2.7	1.5	6.4

450	8.5	11.3		32
500	9.1	11.9		32

Source: Adapted from MSS *Standard* SP-69
*Spacing does not apply where span calculations are made or where concentrated loads are placed between supports such as flanges, valves, specialties, etc.

Support spacings for PVC and CPVC pipe systems are influenced by operating temperatures. Table 12 recommends horizontal spacing based on pipe size, schedule, material (PVC or industrial-grade CPVC), and operating temperature. Hangers and supports should not be clamped tightly because the axial movement of the pipe would be restricted. The charts are based on continuous spans and uninsulated lines carrying liquids. They are not applicable where loads between supports are concentrated (e.g., for valves, flanges) or where there is a change in direction. Hangers/supports should be located adjacent to joints, branch connections, and changes in direction. Risers should be in installed independently of adjacent horizontal hangers/supports.

For cast iron pipe, maximum spacing should be 3.7 m, with at least one hanger/support for each pipe section.

1.7 PIPE EXPANSION AND FLEXIBILITY

Temperature changes cause dimensional changes in all materials. Table 13 shows the coefficients of expansion for metallic piping materials commonly used in HVAC. For systems operating at high temperatures, such as steam and hot water, the rate of expansion is high, and significant movements can occur in short runs of piping. Even though rates of expansion may be low for systems operating in the range of 5 to 40°C, such as chilled and condenser water, they can cause large movements in long runs of piping, which are common in distribution systems and high-rise buildings. Therefore, in addition to design requirements for pressure, mass, and other loads, piping systems must accommodate thermal and other movements to prevent the following:

- Failure of pipe and supports from overstress and fatigue
- Leakage of joints
- Detrimental forces and stresses in connected equipment

An unrestrained pipe operates at the lowest overall stress level. Anchors and restraints are needed to support pipe mass and to protect equipment connections. Anchor forces and bowing of pipe

anchored at both ends are generally too large to be acceptable, so general practice is to **never anchor a straight run of steel pipe at both ends**. Piping must be allowed to expand or contract through thermal changes. Ample flexibility can be attained by designing pipe bends and loops or by including supplemental devices, such as expansion joints.

End reactions transmitted to rotating equipment, such as pumps or turbines, may deform the equipment case and cause bearing misalignment that may ultimately cause the component to fail. Consequently, manufacturers' recommendations on allowable forces and movements that may be placed on their equipment should be followed.

1.8 PIPE BENDS AND LOOPS

Detailed stress analysis requires involved mathematical analysis and is generally performed by computer programs. However, such involved analysis is not typically required for most HVAC systems because the piping arrangements and temperature ranges at which they operate are usually simple to analyze. Expansion stresses discussed in this section relate only to aboveground pipe located in open air, or preinsulated pipe.

L Bends

The guided cantilever beam method of evaluating L bends can be used to design L bends, Z bends, pipe loops, branch take-off connections, and some more complicated piping configurations. The guided cantilever equation [see Equation (17)] is generally conservative because it assumes that the pipe arrangement does not rotate. The anchor force results will be higher because of the lack of rotation, and rigorous analysis is recommended for complicated or expensive systems.

Equation (15) may be used to calculate the length of leg BC needed to accommodate thermal expansion or contraction of leg AB for a guided cantilever beam (Figure 4).

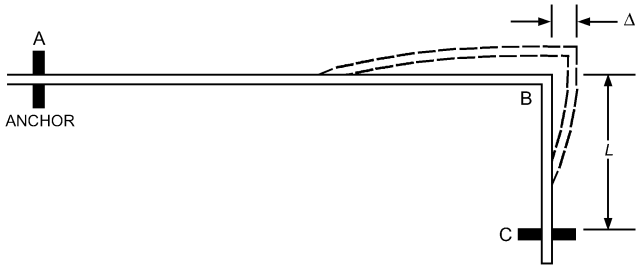

Fig. 4 Guided Cantilever Beam

$$L = \sqrt{\frac{3\Delta DE}{S_A}} \tag{15}$$

where

L = length of leg BC required to accommodate thermal expansion of long leg AB, mm
Δ = thermal expansion or contraction of leg AB, mm
D = actual pipe outside diameter, mm
E = modulus of elasticity, kPa
S_A = allowable stress range, kPa

For the commonly used A53 Grade B seamless or ERW pipe, an allowable stress S_A of 155 MPa (see Table 15) can be used without overstressing the pipe. However, this can result in very high end reactions and anchor forces, especially with large-diameter pipe. Designing to a stress range S_A of 103 MPa and assuming E = 193 GPa, Equation (15) reduces to Equation (16), which provides reasonably low end reactions without requiring too much extra pipe. In addition, Equation (16) may be used with A53 continuous (butt-) welded, seamless, and ERW pipe, and B88 drawn copper tubing.

$$L = 75\sqrt{\Delta D} \tag{16}$$

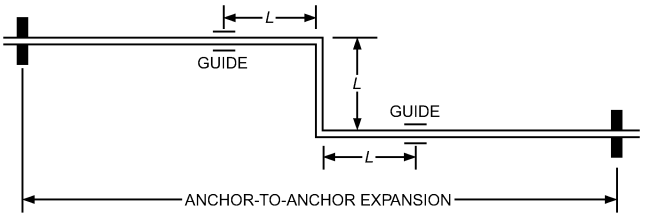
	504	7.31	9.54	9.76

The guided cantilever method of designing L bends assumes no restraints; therefore, care must be taken in supporting the pipe. For horizontal L bends, it is usually necessary to place a support near point B (see Figure 4), and any supports between points A and C must provide minimal resistance to piping movement; this is done by using slide plates or hanger rods of ample length, with hanger components selected to allow for swing no greater than 4°.



For L bends containing both vertical and horizontal legs, any supports on the horizontal leg must be spring hangers designed to support the full mass of pipe at normal operating temperature with a maximum load variation of 25%.

The force developed in an L bend that must be sustained by anchors or connected equipment is determined by the following equation:

$$F = \frac{12E_c I\Delta}{10^6 L^3} \quad (17)$$

where

F = force, kN
E_c = modulus of elasticity, kPa
I = moment of inertia, mm^4
L = length of offset leg, mm
Δ = deflection of offset leg, mm

Distance from guides, if used, to offset should be equal or exceed length of offset.
Offset piping must be supported with hangers, slide plates, and spring hangers similar to those for L bends.

Fig. 5 Z Bend in Pipe

Z Bends

Z bends, as shown in Figure 5, are very effective for accommodating pipe movements. A simple and conservative method of sizing Z bends is to design the offset leg to be 65% of the values used for an L bend in Equation (15):

$$L = 48.7\sqrt{\Delta D} \quad (18)$$

where

L = length of offset leg, mm
Δ = anchor-to-anchor expansion, mm
D = pipe outside diameter, mm

The force developed in a Z bend can be calculated with acceptable accuracy as follows:

$$F = C_1\Delta(D/L)^2 \quad (19)$$

where

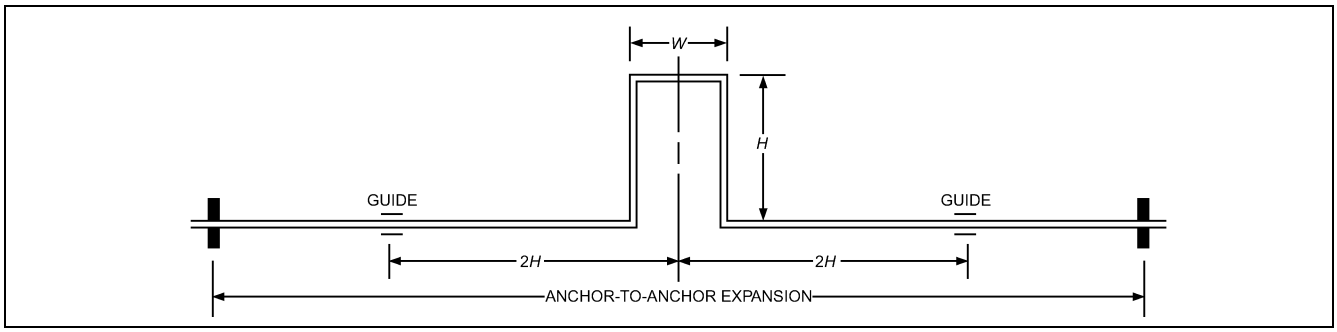
C_1 = 101 kN/mm
F = force, kN
D = pipe outside diameter, mm
L = length of offset leg, mm
Δ = anchor-to-anchor expansion, mm

U Bends and Pipe Loops

Pipe loops or U bends are commonly used in long runs of piping. A simple method of designing pipe loops is to calculate the anchor-to-anchor expansion and, using Equation (15), determine the length L necessary to accommodate this movement. The pipe loop dimensions can then be determined using $W = L/5$ and $H = 2W$.

Note that guides must be spaced no closer than twice the height of the loop, and piping between guides must be supported, as described in the section on L Bends, when the length of pipe between guides exceeds the maximum allowable hanger spacing for the size pipe.

Table 14 lists pipe loop dimensions for pipe sizes 25 to 600 mm and anchor-to-anchor expansion (contraction) of 50 to 300 mm.



No simple method has been developed to calculate pipe loop force; however, it is generally low. A conservative estimate is 35 N per millimetre diameter (e.g., a 50 mm pipe will develop 1.75 kN of force and a 300 mm pipe will develop 10.5 kN of force). Additional analysis should be done for pipes greater than 300 mm in diameter, because other simplified methodologies predict higher anchor forces.

Expansion and Contraction Control of Other Materials

To design expansion and contraction loops and bends for other materials, consult the Copper Development Association (CDA 2010) for copper pipes, and Plastic Pipe and Fitting Association (PPFA 2009) for plastic pipes.

50	0.9	1.8	1.2	2.4	1.5	3.0	1.7	3.4	1.8	3.7	2.1	4.3
80	1.1	2.1	1.5	3.0	1.8	3.7	2.0	4.0	2.3	4.6	2.4	4.9
100	1.2	2.4	1.7	3.4	2.0	4.0	2.3	4.6	2.6	5.2	2.7	5.5
150	1.5	3.0	2.0	4.0	2.4	4.9	2.7	5.5	3.0	6.1	3.4	6.7
200	1.7	3.4	2.3	4.6	2.7	5.5	3.2	6.4	3.7	7.3	4.0	7.9
250	1.8	3.7	2.6	5.2	3.0	6.1	3.5	7.0	4.0	7.9	4.3	8.5
300	2.0	4.0	2.7	5.5	3.4	6.7	3.8	7.6	4.3	8.5	4.7	9.4
350	2.1	4.3	2.9	5.8	3.5	7.0	4.0	7.9	4.6	9.1	4.9	9.8
400	2.3	4.6	3.0	6.1	3.8	7.6	4.3	8.5	4.9	9.8	5.3	10.7
450	2.4	4.9	3.4	6.7	4.0	7.9	4.6	9.1	5.2	10.4	5.6	11.3
500	2.6	5.2	3.5	7.0	4.3	8.5	4.9	9.8	5.5	11.0	5.9	11.9
600	2.7	5.5	3.8	7.6	4.4	8.8	5.3	10.7	5.9	11.9	6.4	12.8

Notes: 1. *W* and *H* dimensions are metres.
2. *L* is determined from Equation (15). $W = L/5$ $H = 2W$ $2H + W = L$
3. Approximate force to deflect loop = 35 N/mm pipe diameter. For example, 200 mm pipe creates 7600 N of force.

Cold Springing of Pipe

Cold springing or cold positioning of pipe consists of offsetting or springing the pipe in a direction opposite the expected movement. Cold springing is not recommended for most HVAC piping. Furthermore, **cold springing does not allow designing a pipe bend or loop for twice the calculated movement**. For example, if a particular L bend can accommodate 75 mm of movement from a neutral position, cold springing does not allow the L bend to accommodate 150 mm of movement.

Analyzing Existing Piping Configurations

Piping is best analyzed using a computer stress analysis program, which can provide all pertinent data, including stress, movements, and loads. Services can perform such analysis if programs are not available in house. However, many situations do not require such detailed analysis. A simple, satisfactory method for single and multiplane systems is to divide the system with real or imaginary anchors into a number of single-plane units, as shown in Figure 6, that can be evaluated as L and Z bends.

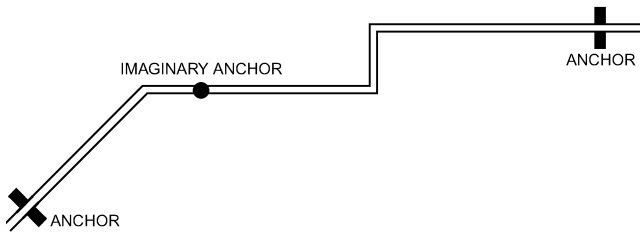

Fig. 6 Multiplane Pipe System

2. PIPE AND FITTING MATERIALS

2.1 PIPE

Steel Pipe

Steel pipe is manufactured by several processes. Seamless pipe (Type S), made by piercing or extruding, has no longitudinal seam. Other manufacturing methods roll a strip or sheet of steel (skelp) into a cylinder and weld a longitudinal seam. A continuous-weld (Type F CW) furnace butt-welding (BW; i.e., welding pipe in a single plane) process forces and joins the edges together at high temperature. An electric current welds the seam in electric-resistance-welded (Type E ERW) pipe. ASTM standards such as A53 and A106 specify steel pipe A and B grades. The A grade has a lower tensile strength and is not widely used.

The ASME pressure piping codes require that a longitudinal joint efficiency factor *E* (Table 15) be applied to each type of seam when calculating the allowable stress. ASME *Standard* B36.10M specifies the dimensional standard for wrought steel pipe.

Steel pipe is manufactured with wall thicknesses identified by schedule or weight class. Although schedule numbers and weight class designations are related, they are not constant for all pipe sizes. United States standard (STD) and Schedule 40 pipe have the same wall thickness through 250 mm NPS. For 300 mm and larger standard weight pipe, the wall thickness remains constant at 10 mm, whereas Schedule 40 wall thickness increases with each size. A similar equality exists between Extra Strong (XS) and Schedule 80 pipe through 200 mm; above 200 mm, XS pipe has a 12.7 mm wall, whereas Schedule 80 increases in wall thickness. Table 16 lists properties of representative steel pipe.

Joints in steel pipe are made by welding or by using threaded, flanged, or grooved fittings or socket welding. Unreinforced welded-in branch connections weaken a main pipeline, and added reinforcement is necessary, unless the excess wall thickness of both mains and branches is sufficient to sustain the pressure.

Table 15 Allowable Stresses[a] for Pipe and Tube

ASTM Specification	Grade	Type	Manufacturing Process	Available Sizes, mm	Minimum Tensile Strength, MPa	Basic Allowable Stress S, MPa	Joint Efficiency Factor E	Allowable Stress[b] S_E, MPa	Allowable Stress Range[c] S_A, MPa
A53 steel	—	F	Cont. weld	15 to 100	310	77.5	0.6	46.5	117
A53 steel	B	S	Seamless	15 to 660	413	103	1.0	103	155
A53 steel	B	E	ERW	50 to 500	413	103	0.85	87.6	155
A106 steel	B	S	Seamless	15 to 660	413	103	1.0	103	155
B88 copper	—	—	Hard drawn	8 to 300	248	62	1.0	62	93.1

[a]Listed stresses are for temperatures to 340°C for steel pipe (to 205°C for Type F) and to 120°C for copper tubing.
[b]To be used for internal pressure stress calculations in Equations (10) and (11).
[c]To be used only for piping flexibility calculations; see Equations (12) and (13).

The ASME *Standard* B31 series gives formulas and guidelines for determining whether reinforcement is required. Such calculations are seldom needed in HVAC applications because (1) the fitting is designed in accordance with a standard listed in the applicable ASME B31 table and used within the pressure and temperature limits of that standard, and (2) fittings such as tees and reinforced outlet fittings provide integral reinforcement.

Type F steel pipe is not allowed for ASME *Standard* B31.5 refrigerant piping.

Copper Tube

Because of their inherent resistance to corrosion and ease of installation, copper and copper alloys are often used in heating, air-conditioning, refrigeration, and water supply installations. The two main standards for copper tube are (1) ASTM *Standard* B88, which includes Types K, L, M, and DWV for water and drain service; and (2) ASTM *Standard* B280, which specifies air-conditioning and refrigeration (ACR) tube for refrigeration service.

Types K, L, M, and DWV designate descending wall thicknesses for copper tube. All types have the same outside diameter (OD) for corresponding sizes. Table 17 lists properties of ASTM B88 copper tube. In the plumbing industry, tube of nominal size approximates the inside diameter. The heating and refrigeration trades specify copper tube by the outside diameter. ACR tubing has a different set of wall thicknesses. Types K, L, and M tube may be hard drawn or annealed (soft) temper.

Copper tubing is joined with soldered or brazed, wrought or cast copper capillary socket-end fittings. See Table 20 for lists pressure/temperature ratings of soldered and brazed joints. Small copper tube is also joined by flare or compression fittings.

Hard-drawn tubing has a higher allowable stress than annealed tubing, but if hard tubing is joined by soldering or brazing, the annealed allowable stress should be used.

Brass pipe and copper pipe are also made in steel pipe thicknesses for threading. High cost has eliminated these materials from the market, except for special applications.

The heating and air-conditioning industry generally uses Types L and M tubing, which have higher internal working pressure ratings than the solder joints used at fittings. Type K may be used with brazed joints for higher pressure-temperature requirements or for direct burial. Type M should be used with care where exposed to potential external damage.

Copper and brass should not be used in ammonia refrigerating systems, or in acidic drains from condensing boilers. The section on Special Systems covers other limitations on refrigerant piping.

Ductile Iron and Cast Iron

Cast-iron soil pipe comes as Class 4000 series. It is not used under pressure because the pipe is not suitable and the joints are not restrained. Cast-iron pipe and fittings typically have bell and spigot ends for lead and oakum joints or elastomer push-on joints. Cast-iron pipe and fittings are also furnished with *no-hub* ends for joining with *no-hub* clamps. Local plumbing codes specify permitted materials and joints.

Ductile iron has now replaced cast iron for pressure pipe. Ductile iron is stronger, less brittle, and similar to cast iron in corrosion resistance. It is commonly used for buried pressure water mains or in other locations where internal or external corrosion is a problem. Joints are made with flanged fittings, mechanical joint (MJ) fittings, or elastomer gaskets for bell and spigot ends. Bell and spigot and MJ joints are not self-restrained, though restrained MJ systems are available. Ductile-iron pipe is made in seven thickness classes for different service conditions. AWWA *Standard* C150/A21.50 covers the proper selection of pipe classes.

Nonmetallic (Plastic)

Selecting a plastic for a specific purpose requires attention to the temperatures, pressures, chemicals, and stresses the piping will be subjected to in the specific application. All are suitable for cold water. Plastic pipe should not be used for compressed gases or compressed air if the pipe's material is subject to brittle failure. For other liquids and chemicals, refer to charts provided by plastic pipe manufacturers and distributors. Table 18 gives properties of the various plastics discussed in this section; the last column gives the relative cost of small pipe in each category. Table 2 lists some applications pertinent to HVAC. The following are brief descriptions of common uses for the various materials.

Plastic piping materials fall into two main categories: thermoplastics and thermosets. Thermoplastics melt and are formed by extruding or molding. They are usually used without reinforcing filaments. Thermosets are cured and cannot be reformed. They are normally used with glass fiber reinforcing filaments.

For the purposes of this chapter, **thermoplastic** piping is made of the following materials:

PVC. Because polyvinyl chloride has the best overall range of properties at the lowest cost, it is the most widely used plastic. It is joined by solvent cementing, threading, or flanging. Gasketed push-on joints are also used for larger sizes. ASTM *Standards* D1784, D1785, and D2665 cover PVC pipe.

CPVC. Chlorinated polyvinyl chloride has the same properties as PVC and can withstand a higher temperature before losing strength. It is joined by the same methods as PVC. ASTM *Standards* D1784 and 1785 discuss CPVC.

PE. Low-density polyethylene (LDPE) is a flexible, low-mass tubing with good low-temperature properties. It is used in the food and beverage industry and for instrument tubing. Joins are mechanical, such as compression fittings or push-on connectors and clamps. See ASTM *Standard* D2239 for details.

HDPE. High-density polyethylene is a tough, weather-resistant material used for large pipelines in the gas industry. Fabricated fittings are available. It is joined by heat fusion for large sizes; flare, compression, or insert fittings can be used on small sizes. ASTM *Standard* D3350 discusses HDPE.

[a]Numbers are schedule numbers per ASME *Standard* B36.10M; ST = Standard; XS = Extra Strong.

[b]T = Thread; W = Weld

[c]Working pressures were calculated per ASME *Standard* B31.9 using furnace butt-weld (continuous weld, CW) pipe through 100 mm and electric resistance weld (ERW) thereafter. The allowance A has been taken as

(1) 12.5% of t for mill tolerance on pipe wall thickness, *plus*

(2)An arbitrary corrosion allowance of 0.64 mm for pipe sizes through NPS 2 and 1.65 mm from NPS 2 1/2 through 20, *plus*

(3) A thread cutting allowance for sizes through NPS 2.

Because the pipe wall thickness of threaded standard pipe is so small after deducting the allowance A, the mechanical strength of the pipe is impaired. It is good practice to limit standard threaded pipe pressure to 620 kPa (gage) for steam and 860 kPa (gage) for water.

[a]When using soldered or brazed fittings, the joint determines the limiting pressure.

[b]Working pressures were calculated using ASME *Standard* B31.9 allowable stresses. A 5% mill tolerance has been used on the wall thickness. Higher tube ratings can be calculated using the allowable stress for lower temperatures.

[c]If soldered or brazed fittings are used on hard-drawn tubing, use the annealed ratings. Full-tube allowable pressures can be used with suitably rated flare or compression-type fittings.

[a] Properties listed are for the specific materials listed; each plastic has other formulations. Consult the manufacturer of the system chosen. These values are for comparative purposes.
[b] Hydrostatic design stress (HDS) is equivalent to allowable design stress.
[c] Based on cost of pipe only, without factoring in fittings, joints, hangers, and labor.
[d] A, B, and C are the three manufacturing processes of PEX pipe. The classifications are not related to a ranking system.

PP. Polypropylene is a low-mass plastic used for pressure applications and also for chemical waste lines, because it is inert to a wide range of chemicals. A broad variety of drainage fittings are available. For pressure uses, regular fittings are made. It is joined by heat fusion. See ASTM *Standards* F2830 and F2389 for details.

ABS. Acrylonitrile butadiene styrene is a high-strength, impact- and weather-resistant material. Some formulations can be used for beverage industry. A wide range of fittings is available. It is joined by solvent cement, threading, or flanging. ASTM *Standards* D2661 and D3965 cover ABS.

PVDF. Polyvinylidene fluoride is widely used for ultrapure water systems and in the pharmaceutical industry and has a wide temperature range. This material is over 20 times more expensive than PVC. It is joined by heat fusion, and fittings are made for this purpose. For smaller sizes, mechanical joints can be used. See ASTM *Standard* D2122 for information on PVDF.

Thermosetting piping used in HVAC is called (1) reinforced thermosetting resin (RTR) and (2) fiberglass-reinforced plastic (FRP). RTR and FRP are interchangeable and refer to pipe and fittings commonly made of (1) fiberglass-reinforced epoxy resin, (2) fiberglass-reinforced vinyl ester, and (3) fiberglass-reinforced polyester.

Pipe and fittings made from epoxy resin are generally stronger and operate at a higher temperature than those made from polyester or vinyl ester resins, so they are more likely to be used in HVAC.

PEX. Cross-linked polyethylene is made from high-density polyethylene (HDPE) and contains cross-linked bonds in the polymer structure. This changes the thermoplastic to a thermoset. It can be used up to 150°C. PEX is used in building services pipework systems, hydronic radiant heating and cooling systems, and domestic water piping. PEX comes in two types: barrier and nonbarrier. The barrier, a thin sheet of aluminum between layers of PEX material or a layer of polymer film, prevents oxygen dissolved in water from diffusing through the pipe and corroding metal components. Nonbarrier PEX is acceptable for plumbing systems. PEX can be ordered as A, B, or C (these designations refer to the manufacturing process and not the pipe's structural or chemical properties). All PEX tubing (A, B, C) comply with the same standards: refer to ASTM *Standards* F876, F877, and F2023; CSA *Standard* B137.5; and NSF/ANSI *Standards* 14 and 61 for further information.

2.2 FITTINGS

Table 19 lists standards that give dimensions and pressure ratings for fittings, flanges, and flanged fittings. These data are also available from manufacturers' catalogs.

2.3 JOINING METHODS

Threading

Threading as per ASME *Standard* B1.202M is the most common method for joining small-diameter steel or brass pipe. Pipe with a wall thickness less than standard should not be threaded. ASME *Standard* B31.5 limits the threading for various refrigerants and pipe sizes.

Soldering and Brazing

Copper tube is usually joined by soldering or brazing socket end fittings. Brazing materials melt above 540°C and produce a stronger joint than solder. Table 20 lists soldered and brazed joint strengths. ASME *Standard* B16.22-specified wrought copper solder joint fittings and ASME *Standard* B16.18-specified cast copper solder joint fittings are pressure rated the same way as annealed Type L copper

[a]Wrought steel butt-welding fittings are made to match steel pipe wall thicknesses and are rated at the same working pressure as seamless pipe. Flanges and flanged fittings are rated by working steam pressure classes. Forged steel fittings are rated from 14 to 41 MPa in classes and are used for high-temperature and high-pressure service for small pipe sizes.
[b]Class numbers refer to maximum working saturated steam gage pressure (in pounds per square inch. Multiply these values by 6.9 to convert to kilopascals). For liquids at lower temperatures, higher pressures are allowed. Groove-end fittings of these materials are made by various manufacturers who publish their own ratings.
[c]Classes refer to maximum working steam gage pressure (in pounds per square inch. Multiply these values by 6.9 to convert to kilopascals). At ambient temperatures, higher liquid pressures are allowed. Solder joint fittings are limited by the strength of the soldered or brazed joint (see Table 20).
[d]Ratings of plastic fittings match the pipe of corresponding schedule number.

Source: Based on ASME *Standard* B31.9
[a]Solder joints are not to be used for
(1) Flammable or toxic gases or liquids
(2) Gas, vapor, or compressed air in tubing over 100 mm, unless maximum pressure is limited to 140 kPa (gage).
[b]Lead solders must not be used in potable-water systems.
[c]Tin/antimony solder is allowed for potable-water supplies in some jurisdictions.
[d]Rated pressure for temperatures up to 93°C is that of the tube being joined.

tube of the same size. Health concerns have caused many jurisdictions to ban solder containing lead or antimony for joining pipe in potable-water systems. Lead-based solder, in particular, must not be used for potable water.

Flared and Compression Joints

Flared and compression fittings can be used to join copper, steel, stainless steel, and aluminum tubing. Properly rated fittings can keep the joints as strong as the tube.

Flanges

Flanges can be used for large pipe and all piping materials. They are commonly used to connect to equipment and valves, and wherever the joint must be opened to allow service or replacement of components. For steel pipe, flanges are available in pressure ratings to 17 MPa. High-tensile-strength bolts must be used for high-pressure flanged joints.

For welded pipe, weld neck, slip-on, or socket weld flanges are available. Thread-on flanges are available for threaded pipe.

Licensed for single user. © 2021 ASHRAE, Inc.

Flanges are generally flat faced or raised face. Flat-faced flanges with full-faced gaskets are most often used with cast iron and materials that cannot take high bending loads. Raised-face flanges with ring gaskets are preferred with steel pipe because they facilitate increasing the sealing pressure on the gasket to help prevent leaks. Other facings, such as O ring and ring joint, are available for special applications.

All flat-faced, raised-face, and lap-joint flanges require a gasket between the mating flange surfaces. Gaskets are made from rubber, synthetic elastomers, cork, fiber, plastic, polytetrafluoroethylene (PTFE), metal, and combinations of these materials. The gasket must be compatible with the flowing media and the temperatures at which the system operates.

Welding

Welded-steel pipe joints offer the following advantages:

- Do not age, dry out, or deteriorate as gasketed joints do
- Can accommodate greater vibration and water hammer and higher temperatures and pressures than other joints
- For critical service, can be tested by several nondestructive examination (NDE) methods, such as radiography or ultrasound
- Provide maximum long-term reliability

The applicable sections of the ASME *Standard* B31 series and the ASME *Boiler and Pressure Vessel Code* give rules for welding. ASTM *Standard* B31 requires that all welders and welding procedure specifications (WPS) be qualified. Separate WPS are needed for different welding methods and materials. The qualifying tests and the variables requiring separate procedure specifications are set forth in the ASME *Boiler and Pressure Vessel Code*, Section IX. The manufacturer, fabricator, or contractor is responsible for the welding procedure and welders. ASME *Standard* B31.9 requires visual examination of welds and outlines limits of acceptability.

The following welding processes are often used in the HVAC industry:

- **Shielded metal arc welding (SMAW)**, also called stick welding): the molten weld metal is shielded by vaporization of the electrode coating.
- **Gas metal arc welding (GMAW)**, also called **metal inert gas (MIG) welding**: the electrode is a continuously fed wire shielded by argon or carbon dioxide gas from the welding gun nozzle.
- **Gas tungsten arc welding (GTAW)**, also called **tungsten insert gas (TIG) welding**: this process uses a nonconsumable tungsten electrode surrounded by a shielding gas. The weld material may be provided from a separate noncoated rod.

Integrally Reinforced Outlet Fittings

Integrally reinforced outlet fittings are used to make branch and take-off connections and are designed to allow welding directly to pipe without supplemental reinforcing. Fittings are available with threaded, socket welded, or butt-weld outlets.

Solvent Cement

Solvent cement welds nonmetallic pipe together by softening surface of the materials being joined. It is different from gluing, which hardens and holds the material together. Sometimes this join is called a **solvent-welded joint**.

Rolled-Groove Joints

Grooved joints require special grooved fittings and a shallow groove cut or rolled into the pipe end. These joints can be used with steel, cast iron, ductile iron, copper, and plastic pipes. A segmented clamp engages the grooves and a special gasket uses internal pressure to tighten the seal. Some clamps are designed with clearance between tongue and groove to accommodate misalignment and thermal movements, and others are designed to limit movement and provide a rigid system. Manufacturers' data give temperature and pressure limitations.

Bell-and-Spigot Joints

A bell-and-spigot joint is mechanical joint consists of a **sleeve** slightly larger than the outside diameter of the pipe. The pipe ends are inserted into the sleeve, and gaskets are packed into the annular space between the pipe and coupling and held in place by retainer rings. This type of joint can accept some axial misalignment, but it must be anchored or otherwise restrained to prevent axial pullout or lateral movement. Manufacturers provide pressure/temperature data.

Press-Connect (Press Fit) Joints

These joints rely on an elastomeric gasket or seal and an approved pressing tool and jaws to seal the joint.

Push-Connect Joints

Push-connect joining use and integral elastomeric seal or gasket and stainless steel ring to make a leak-free joint. There are two common types, both of which form strong, permanent joints: one type is removable for servicing, and the other type is not easily removed after installation.

Unions

Unions allow disassembly of threaded pipe systems. Unions are three-part fittings with a mating machined seat on the two parts that thread onto the pipe ends. A threaded locking ring holds the two ends tightly together. A union also allows threaded pipe to be turned at the last joint connecting two pieces of equipment. Companion flanges (a pair) for small pipe serve the same purpose.

2.4 EXPANSION JOINTS AND EXPANSION COMPENSATING DEVICES

Although the inherent flexibility of the piping should be used to the maximum extent possible, expansion joints must be used where movements are too large to accommodate with pipe bends or loops or where insufficient room exists to construct a loop of adequate size. Typical situations are tunnel piping and risers in high-rise buildings, especially for steam and hot-water pipes where large thermal movements are involved.

Packed and packless expansion joints and expansion compensating devices are used to accommodate movement, either axially or laterally.

In the **axial method** of accommodating movement, the expansion joint is installed between anchors in a straight-line segment and accommodates axial motion only. This method has high anchor loads, primarily because of pressure thrust. It requires careful guiding, but expansion joints can be spaced conveniently to limit movement of branch connections. The axial method finds widest application for long runs without natural offsets, such as tunnel and underground piping and risers in tall buildings.

The **lateral** or **offset method** requires the device to be installed in a leg perpendicular to the expected movement and accommodates lateral movement only. This method generally has low anchor forces and minimal guide requirements. It finds widest application in lines with natural offsets, especially where there are few or no branch connections.

Packed expansion joints depend on slipping or sliding surfaces to accommodate the movement and require some type of seals or packing to seal the surfaces. Most such devices require some maintenance but are not subject to catastrophic failure. Further, with most packed expansion joint devices, any leaks that develop can be repacked under full line pressure without shutting down the system.

Packless expansion joints depend on the flexing or distortion of the sealing element to accommodate movement. They generally do

Licensed for single user. © 2021 ASHRAE, Inc.

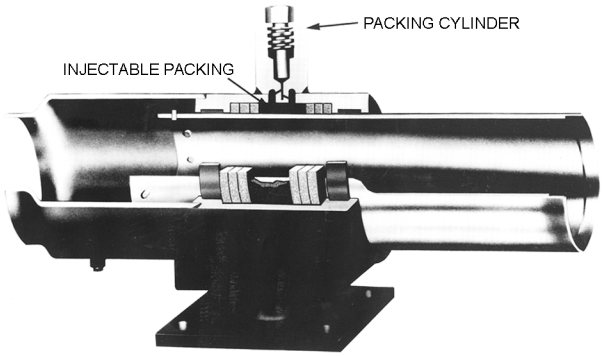

Fig. 7 Packed Slip Expansion Joint

not require any maintenance, but maintenance or repair is not usually possible. If a leak occurs, the system must be shut off and drained, and the entire device must be replaced. Further, catastrophic failure of the sealing element can occur and, although likelihood of such failure is remote, it must be considered in certain design situations.

Packed expansion joints are preferred where long-term system reliability is of prime importance (using types that can be repacked under full line pressure) and where major leaks can be life threatening or extremely costly. Typical applications are risers, tunnels, underground pipe, and distribution piping systems. Packless expansion joints are generally used where even small leaks cannot be tolerated (e.g., for gas and toxic chemicals), where temperature limitations preclude the use of packed expansion joints, and for very-large-diameter pipe where packed expansion joints cannot be constructed or the cost would be excessive.

In all cases, expansion joints should be installed, anchored, and guided in accordance with expansion joint manufacturers' recommendations.

Packed Expansion Joints

There are two types of packed expansion joints: packed slip expansion joints and flexible ball joints.

Packed Slip Expansion Joints. These are telescoping devices designed to accommodate axial movement only. Packing seals the sliding surfaces. The original packed slip expansion joint used multiple layers of braided compression packing, similar to the stuffing box commonly used with valves and pumps; this arrangement requires shutting and draining the system for maintenance and repair. Advances in design and packing technology have eliminated these problems, and most current packed slip joints use self-lubricating semiplastic packing, that can be injected under full line pressure without shutting off the system (Figure 7). (Many manufacturers use asbestos-based packings, unless requested otherwise. Asbestos-free packings, such as flake graphite, are available and, although more expensive, should be specified in lieu of products containing asbestos.)

Standard packed slip expansion joints are constructed of carbon steel with weld or flange ends in sizes 40 to 910 mm for pressures up to 2.1 MPa and temperatures up to 425°C. Larger, higher-temperature, and higher-pressure designs are available. Standard single joints are generally designed for 100, 200, or 300 mm axial traverse; double joints with an intermediate anchor base can accommodate twice these movements. Special designs for greater movements are available.

Flexible Ball Joints. These joints are used in pairs to accommodate lateral or offset movement and must be installed in a leg perpendicular to the expected movement. The original flexible ball joint design incorporated only inner and outer containment seals that could not be serviced or replaced without removing the ball joint from the system. The packing technology of the packed slip expansion joint, explained previously, has been incorporated into the flexible ball joint design; now, packed flexible ball joints have self-lubricating semiplastic packing that can be injected under full line pressure without shutting off the system (Figure 8).

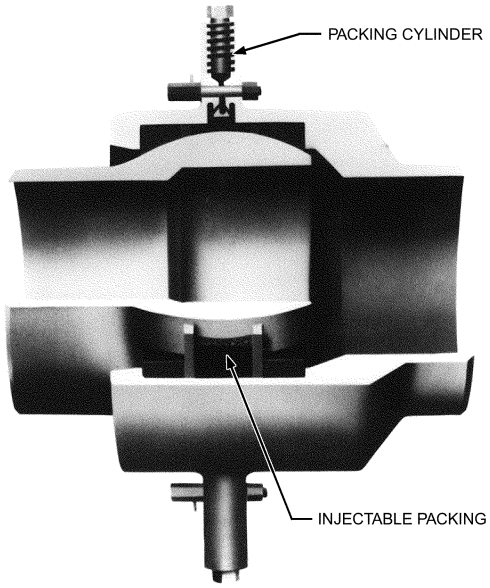

Fig. 8 Flexible Ball Joint

Standard flexible ball joints are available in sizes 32 to 760 mm with threaded (32 to 50 mm), weld, and flange ends for pressures to 2.1 MPa and temperatures to 400°C. Flexible ball joints are available in larger sizes and for higher temperature and pressure ranges.

Packless Expansion Joints

Types include metal bellows expansion joints, rubber expansion joints, and flexible hose or pipe connectors.

Metal Bellows Expansion Joints. These expansion joints have a thin-walled convoluted section that accommodates movement by bending or flexing. The bellows material is generally Type 304, 316, or 321 stainless steel, but other materials are commonly used to satisfy service conditions. Small-diameter expansion joints 20 to 80 mm are generally called **expansion compensators** and are available in all-bronze or steel construction. Metal bellows expansion joints can generally be designed for the pressures and temperatures commonly encountered in HVAC systems and can also be furnished in rectangular configurations for ducts and chimney connectors.

Overpressurization, improper guiding, and other forces can distort the bellows element. For low-pressure applications, such distortion can be controlled by the geometry of the convolution or the thickness of the bellows material. For higher pressure, internally pressurized joints require reinforcing. Externally pressurized designs are not subject to such distortion and are not generally furnished without supplemental bellows reinforcing.

Single- and double-bellows expansion joints primarily accommodate axial movement only, similar to packed slip expansion joints. Although bellows expansion joints can accommodate some lateral movement, the **universal tied bellows expansion joint** better accommodates large lateral movement. This device operates much like a pair of flexible ball joints, except that bellows elements are used instead of flexible ball elements. The tie rods on this joint contain the pressure thrust, so anchor loads are much lower than with axial-type expansion joints.

Rubber Expansion Joints. Similar to single-metal bellows expansion joints, rubber expansion joints incorporate a nonmetallic elastomeric bellows sealing element and generally have more stringent temperature and pressure limitations. Although rubber expansion joints can be used to accommodate expansion and contraction of the piping, they are primarily used as flexible connectors at equipment to isolate sound and vibration and eliminate stress at equipment nozzles.

Flexible Hose. This type of hose can be constructed of elastomeric material or corrugated metal with an outer braid for reinforcing and end restraint. Flexible hose is primarily used as a flexible connector at equipment to isolate sound and vibration and eliminate stress at equipment nozzles; however, flexible metal hose is well suited for use as an **offset-type expansion joint**, especially for copper tubing and branch connections off risers.

3. APPLICATIONS

3.1 WATER PIPING

Flow Rate Limitations

Stewart and Dona (1987) surveyed the literature relating to water flow rate limitations. Noise, erosion, and installation and operating costs all limit the maximum and minimum velocities in piping systems. If piping sizes are too small, noise levels, erosion levels, and pumping costs can be unfavorable. If piping sizes are too large, installation costs are excessive. Therefore, pipe sizes are chosen to minimize initial cost while avoiding the undesirable effects of high velocities. ASHRAE *Standard* 90.1 has been accepted by authorities having jurisdiction (AHJs) as a code and, as such, limits the flow for energy conservation. The table (Table 21) is reproduced with modification showing velocity limitations.

Various upper limits of water velocity and/or pressure drop in piping and piping systems are used. One recommendation places a velocity limit of 1.2 m/s for 50 mm pipe and smaller, and a pressure drop limit of 400 Pa/m for piping over 50 mm. Other guidelines are based on the type of service (Table 22) or annual operating hours (Table 23). These limitations are imposed either to control the levels of pipe and valve noise, erosion, and water hammer pressure or for economic reasons. Carrier (1960) recommends that the velocity not exceed 4.6 m/s in any case.

Noise Generation

Velocity-dependent noise in piping and piping systems results from any or all of four sources: turbulence, cavitation, release of entrained air, and water hammer. In investigations of flow-related noise, Ball and Webster (1976), Marseille (1965), and Rogers (1953, 1954, 1956) reported that velocities on the order of 3 to 5 m/s lie within the range of allowable noise levels for residential and commercial buildings. The experiments showed considerable variation in noise levels obtained for a specified velocity. Generally, systems with longer pipe and with more numerous fittings and valves were noisier. In addition, sound measurements were taken under widely differing conditions; for example, some tests used plastic-covered pipe, whereas others did not. Thus, no detailed correlations relating sound level to flow velocity in generalized systems are available.

Noise generated by fluid flow in a pipe increases sharply if cavitation or release of entrained air occurs. Usually, the combination of high water velocity with a change in flow direction or a decrease in pipe cross section, causing a sudden pressure drop, is necessary to cause cavitation. Ball and Webster (1976) found that at their maximum velocity of 13 m/s, cavitation did not occur in straight 10 and 15 mm pipe; using the apparatus with two elbows, cold-water velocities up to 6.5 m/s caused no cavitation. Cavitation did occur in orifices of 1:8 area ratio (orifice flow area is one-eighth of pipe flow area) at 1.5 m/s and in 1:4 area ratio orifices at 3 m/s (Rogers 1954).

Some data are available for predicting hydrodynamic (liquid) noise generated by control valves. The International Society of Automation compiled prediction correlations in an effort to develop control valves for reduced noise levels (ISA 2007). The correlation to predict hydrodynamic noise from control valves is

$$SL = 10 \log A_v + 20 \log \Delta p - 30 \log t + 76.6 \quad (20)$$

Licensed for single user. © 2021 ASHRAE, Inc.

where

SL = sound level, dB
A_v = valve coefficient, $m^3/(s \cdot Pa)^{0.5}$
Q = flow rate, m^3/s
Δp = pressure drop across valve, Pa
t = downstream pipe wall thickness, mm

Air entrained in water usually has a higher partial pressure than the water. Even when flow rates are small enough to avoid cavitation, the release of entrained air may create noise. Every effort should be made to vent the piping system or otherwise remove entrained air.

Erosion

Erosion in piping systems is caused by water bubbles, sand, or other solid matter impinging on the inner surface of the pipe. Generally, at velocities lower than 3 m/s, erosion is not significant as long as there is no cavitation. When solid matter is entrained in the fluid at high velocities, erosion occurs rapidly, especially in bends. Thus, high velocities should not be used in systems where sand or other solids are present or where slurries are transported.

Allowances for Aging

With age, the internal surfaces of pipes become increasingly rough. This reduces the available flow with a fixed pressure supply. However, designing with excessive age allowances may result in oversized piping. Age-related decreases in capacity depend on type of water, type of pipe material, temperature of water, and type of system (open or closed) and include

- Sliming (biological growth or deposited soil on the pipe walls): occurs mainly in unchlorinated, raw water systems.
- Caking of calcareous salts: occurs in hard water (i.e., water bearing calcium salts) and increases with water temperature.
- Corrosion (incrustations of ferrous and ferric hydroxide on the pipe walls): occurs in metal pipe in soft water. Because oxygen is necessary for corrosion to take place, significantly more corrosion takes place in open systems.

Allowances for expected decreases in capacity are sometimes treated as a specific amount (percentage). Dawson and Bowman (1933) added an allowance of 15% friction loss to new pipe (equivalent to an 8% decrease in capacity). The *HDR Design Guide* (1981) increased the friction loss by 15 to 20% for closed piping systems and 75 to 90% for open systems. Carrier (1960) indicates a factor of approximately 1.75 between friction factors for closed and open systems.

Obrecht and Pourbaix (1967) differentiated between the corrosive potential of different metals in potable water systems and concluded that iron is the most severely attacked, then galvanized steel, lead, copper, and finally copper alloys (e.g., brass). Freeman (1941) and Hunter (1941) showed the same trend. After four years of cold- and hot-water use, copper pipe had a capacity loss of 25 to 65%. Aged ferrous pipe has a capacity loss of 40 to 80%. Smith (1983) recommended increasing the design discharge by 1.55 for uncoated cast iron, 1.08 for iron and steel, and 1.06 for cement or concrete.

The Plastic Pipe Institute (1971) found that corrosion is not a problem in plastic pipe; the capacity of plastic pipe in Europe and the United States remains essentially the same after 30 years in use.

Extensive age-related flow data are available for use with the Hazen-Williams empirical equation. Difficulties arise in its application, however, because the original Hazen-Williams roughness coefficients are valid only for the specific pipe diameters, water velocities, and water viscosities used in the original experiments. Thus, when the *C*s are extended to different diameters, velocities, and/or water viscosities, errors of up to about 50% in pipe capacity can occur (Sanks 1978; Williams and Hazen 1933).

Water Hammer

When any moving fluid (not just water) is abruptly stopped, as when a valve closes suddenly, large pressures can develop. Although detailed analysis requires knowledge of the elastic properties of the pipe and the flow-time history, the limiting case of rigid pipe and instantaneous closure is simple to calculate. Under these conditions,

$$\Delta p_h = \rho c_s V \tag{21}$$

where

Δp_h = pressure rise caused by water hammer, Pa
ρ = fluid density, kg/m^3
c_s = velocity of sound in fluid, m/s
V = fluid flow velocity, m/s

The c_s for water is 1439 m/s, although the pipe's elasticity reduces the effective value.

Example 3. What is the maximum pressure rise if water flowing at 3 m/s is stopped instantaneously?

Solution: $\Delta p_h = 1000 \times 1439 \times 3 = 4.32$ MPa

3.2 SERVICE WATER PIPING

Sizing service water piping differs from sizing process lines in that design flows in service water piping are determined by the probability of simultaneous operation of multiple individual loads such as water closets, urinals, lavatories, sinks, and showers. The full-flow characteristics of each load device are readily obtained from manufacturers; however, service water piping sized to handle all load devices simultaneously would be seriously oversized. Thus, a major issue in sizing service water piping is to determine the diversity of the loads.

The procedure shown in this chapter uses the work of R.B. Hunter for estimating diversity (Hunter 1940, 1941). The present-day plumbing designer is usually constrained by building or plumbing codes, which specify the individual and collective loads to be used for pipe sizing. Frequently used codes (including the ICC *International Plumbing Code* and the PHCC *National Standard Plumbing Code*) contain procedures quite similar to those shown here. The designer must be aware of the applicable code for the location being considered.

Federal mandates are forcing plumbing fixture manufacturers to reduce design flows to many types of fixtures, but these may not yet be included in locally adopted codes. Also, the designer must be aware of special considerations; for example, toilet usage at sports arenas will probably have much less diversity than codes allow and thus may require larger supply piping than the minimum specified by codes.

Table 24 gives the rate of flow desirable for many common fixtures and the average pressure necessary to give this rate of flow. Pressure varies with fixture design.

In estimating load, the rate of flow is frequently computed in **fixture units** that are relative indicators of flow. Table 25 gives the demand weights in terms of fixture units for different plumbing fixtures under several conditions of service, and Figure 9 gives the estimated demand corresponding to any total number of fixture units. Figures 10 and 11 provide more accurate estimates at the lower end of the scale.

The estimated demand load for fixtures used intermittently on any supply pipe can be obtained by multiplying the number of each kind of fixture supplied through that pipe by its weight from Table 25, adding the products, and then referring to the appropriate curve of Figure 9, 10, or 11 to find the demand corresponding to the total fixture units. In using this method, note that the demand for fixture or supply outlets other than those listed in the table of fixture units is not yet included in the estimate. The demands for outlets (e.g., hose connections and air-conditioning apparatus) that are likely to impose

Source: Hunter (1941).
[a]For supply outlets likely to impose continuous demands, estimate continuous supply separately, and add to total demand for fixtures.
[b]For fixtures not listed, weights may be assumed by comparing fixture to listed one using water in similar quantities and at similar rates.
[c]Given weights are for total demand. For fixtures with both hot- and cold-water supplies, weights for maximum separate demands can be assumed to be 75% of listed demand for the supply.

continuous demand during heavy use of the weighted fixtures should be estimated separately and added to demand for fixtures used intermittently to estimate total demand.

The Hunter curves in Figures 9, 10, and 11 are based on use patterns in residential buildings and can be erroneous for other usages such as sports arenas. Williams (1976) discusses the Hunter assumptions and presents an analysis using alternative assumptions.

So far, the information presented shows the *design rate of flow* to be determined in any particular section of piping. The next step is to determine the *size* of piping. As water flows through a pipe, the pressure continually decreases along the pipe because of loss of energy from friction. The problem is then to ascertain the minimum pressure in the street main and the minimum pressure required to operate the topmost fixture. (A pressure of 100 kPa may be ample for most flush valves, but manufacturers' requirements should be consulted. Some fixtures require a pressure up to 175 kPa. A minimum of 55 kPa should be allowed for other fixtures.) The pressure differential

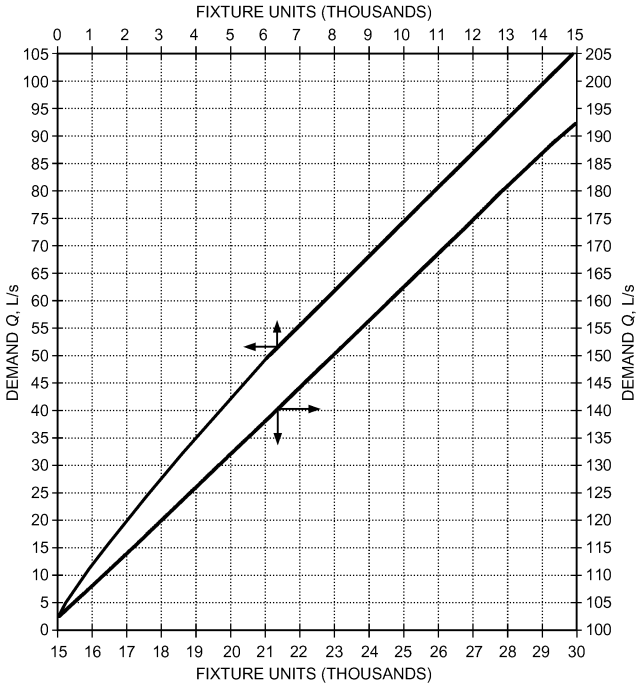

Fig. 9 Demand Versus Fixture Units, Mixed System, High Part of Curve
(Adapted from Hunter 1941)

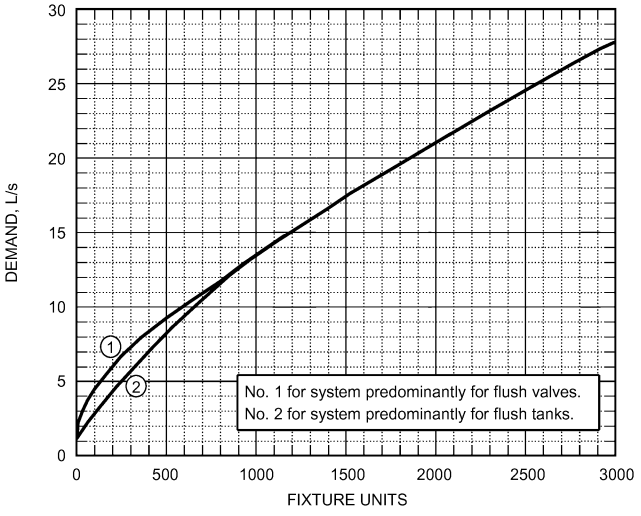

Fig. 10 Estimate Curves for Demand Load
(Adapted from Hunter 1941)

overcomes pressure losses in the distributing system and the difference in elevation between the water main and the highest fixture.

The pressure loss (in kPa) resulting from the difference in elevation between the street main and the highest fixture can be obtained by multiplying the difference in elevation in metres by the conversion factor 9.8.

Pressure losses in the distributing system consist of pressure losses in the piping itself, plus the pressure losses in the pipe fittings, valves, and the water meter, if any. Approximate design pressure losses and flow limits for disk-type meters for various rates of flow are given in Figure 12. Water authorities in many localities

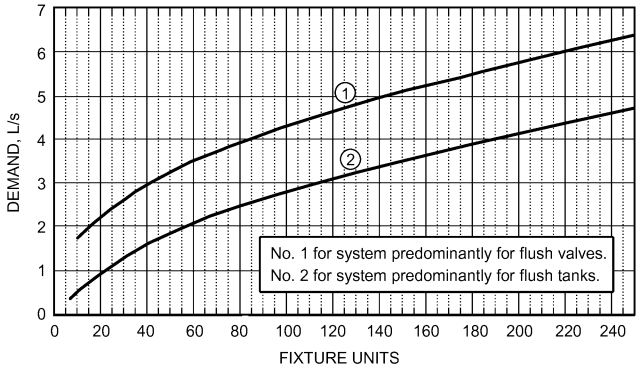

Fig. 11 Section of Figure 10 on Enlarged Scale

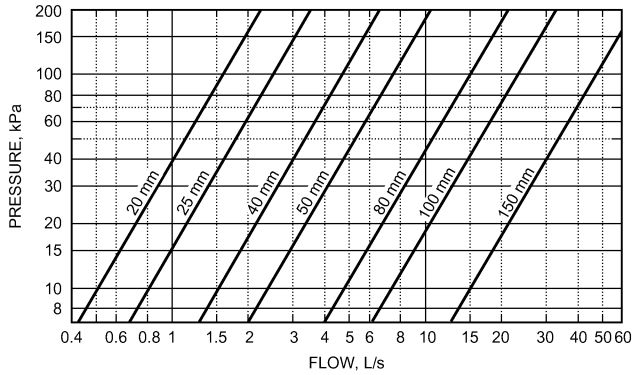

Fig. 12 Pressure Losses in Disk-Type Water Meters

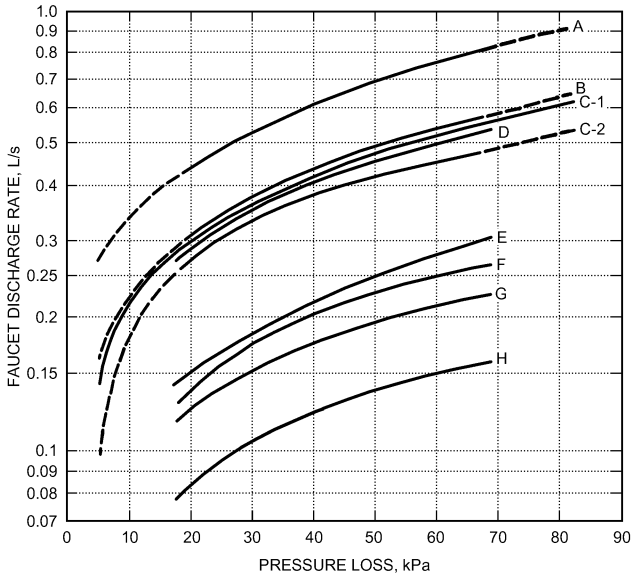

require compound meters for greater accuracy with varying flow; consult the local utility. Design data for compound meters differ from the data in Figure 12. Manufacturers give data on exact pressure losses and capacities.

Figure 13 shows the variation of pressure loss with rate of flow for various faucets and cocks. The water demand for hose bibbs or other large-demand fixtures taken off the building main frequently results in inadequate water supply to the upper floor of a building. This condition can be prevented by sizing the distribution system so that pressure drops from the street main to all fixtures are the same. An ample building main (not less than 25 mm where possible) should be maintained until all branches to hose bibbs have been connected. Where street main pressure is excessive and a pressure-reducing valve is used to prevent water hammer or excessive pressure at fixtures, hose bibbs should be connected ahead of the reducing valve.

The principles involved in sizing upfeed and downfeed systems are the same. In the downfeed system, however, the difference in elevation between the overhead supply mains and the fixtures provides the pressure required to overcome pipe friction. Because friction pressure loss and height pressure loss are not additive, as in an upfeed system, smaller pipes may be used with a downfeed system.

Plastic Pipe

The maximum safe water velocity in a thermoplastic piping system under most operating conditions is typically 1.5 m/s; however, higher velocities can be used in cases where the operating characteristics of valves and pumps are known so that sudden changes in flow velocity can be controlled. The total pressure in the system at any time (operating pressure plus surge of water hammer) should not exceed 150% of the pressure rating of the system.

Fig. 13 Variation of Pressure Loss with Flow Rate for Various Faucets and Cocks

Procedure for Sizing Cold-Water Systems

The recommended procedure for sizing piping systems is as follows:

1. Sketch the main lines, risers, and branches, and indicate the fixtures to be served. Indicate the rate of flow of each fixture.
2. Using Table 25, compute the demand weights of the fixtures in fixture units.
3. Determine the total demand in fixture units and, using Figure 9, 10, or 11, find the expected demand.
4. Determine the equivalent length of pipe in the main lines, risers, and branches. Because the sizes of the pipes are not known, the exact equivalent length of various fittings cannot be determined. Add the equivalent lengths, starting at the street main and proceeding along the service line, main line of the building, and up the riser to the top fixture of the group served.
5. Determine the average minimum pressure in the street main and the minimum pressure required for operation of the topmost fixture, which should be 50 to 175 kPa above atmospheric.
6. Calculate the approximate design value of the average pressure drop per unit length of pipe in equivalent length determined in step 4 and using Equation (1).

$$\Delta p = (p_s - 9.8H - p_f - p_m)/L$$

where

Δp = average pressure loss per metre of equivalent length of pipe, kPa
p_s = pressure in street main, kPa
p_f = minimum pressure required to operate topmost fixture, kPa
p_m = pressure drop through water meter, kPa
H = height of highest fixture above street main, m
L = equivalent length determined in step 4, m

If the system is downfeed supply from a gravity tank, height of water in the tank, converted to kPa by multiplying by 9.8, replaces the street main pressure, and the term $9.8H$ is added

Licensed for single user. © 2021 ASHRAE, Inc.

instead of subtracted in calculating Δp. In this case, H is the vertical distance of the fixture below the bottom of the tank. The pressure conversion factor 9.8 is determined by the mass of water occupying a 1 m^3 volume, or 9800 N/m^2 (9.8 kPa/m).

7. From the expected rate of flow determined in step 3 and the value of Δp calculated in step 6, choose the sizes of pipe from Figure 14, 15, or 16.

Example 4. Assume a minimum street main pressure of 375 kPa; a height of topmost fixture (a urinal with flush valve) above street main of 15 m; an equivalent pipe length from water main to highest fixture of 30 m; a total load on the system of 50 fixture units; and that the water closets are flush valve operated. Find the required size of supply main.

Solution: Use Equation (1):

$$\Delta p = (p_s - 9.8H - p_f - p_m)/L$$

p_s = Street main pressure (given) = 375 kPa
H = 15 m (given)
P_f = 105 kPa from Table 24
Flow = 3.2 L/s from Figure 11

For a trial run, use 40 mm; then P_m = 45 kPa from Figure 12 at 3.2 L/s. The pressure drop available for overcoming friction in pipes and fittings is 375 – 9.8 × 15 – 105 – 45 = 78 kPa.

At this point, estimate the equivalent pipe length of the fittings on the direct line from the street main to the highest fixture. The exact equivalent length of the various fittings cannot be determined because the pipe sizes of the building main, riser, and branch leading to the highest fixture are not yet known, but a first approximation is necessary to tentatively select pipe sizes. If the computed pipe sizes differ from those used in determining the equivalent length of pipe fittings, a recalculation using the computed pipe sizes for the fittings will be necessary. It is common practice for the first trial to assume that the total equivalent length of the pipe fittings is 50% of the total length of pipe. In this example, 30 m × 50% = 15 m.

The permissible pressure loss per metre of equivalent pipe is 78/(30 + 15) = 1.7 kPa/m. A 40 mm building main is adequate.

The sizing of the branches of the building main, the risers, and the fixture branches follows these principles. For example, assume that one of the branches of the building main carries the cold-water supply for three water closets, two bathtubs, and three lavatories. Using the permissible pressure loss of 1.7 kPa/m, the size of branch (determined from Table 25 and Figures 14 and 11) is found to be 40 mm. Items included in the computation of pipe size are as follows:

Fixtures, No. and Type	Fixture Units (Table 25 and Note c)			Demand (Figure 11)	Pipe Size (Figure 14)
3 flush valves	3 × 6	=	18		
2 bathtubs	0.75 × 2 × 2	=	3		
3 lavatories	0.75 × 3 × 1	=	2.25		
Total		=	23.25	2.4 L/s	40 mm

Table 26 is a guide to minimum pipe sizing where flush valves are used.

Velocities exceeding 3 m/s cause undesirable noise in the piping system. This usually governs the size of larger pipes in the system, whereas in small pipe sizes, the friction loss usually governs the selection because the velocity is low compared to friction loss. Velocity is the governing factor in downfeed systems, where friction loss is usually neglected. Velocity in branches leading to pump suctions should not exceed 1.5 m/s.

If the street pressure is too low to adequately supply upper-floor fixtures, the pressure must be increased. Constant- or variable-speed booster pumps, alone or in conjunction with gravity supply tanks, or hydropneumatic systems may be used.

Flow control valves for individual fixtures under varying pressure conditions automatically adjust flow at the fixture to a predetermined quantity. These valves allow the designer to (1) limit flow at the individual outlet to the minimum suitable for the purpose, (2) hold total demand for the system more closely to the required minimum, and (3) design the piping system as accurately as is practicable for the requirements.

Hydronic System Piping

The Darcy-Weisbach equation with friction factors from the Moody chart or Colebrook equation (or, alternatively, the Hazen-Williams equation) is fundamental to calculating pressure drop in hot- and chilled-water piping; however, charts calculated from these equations (such as Figures 14, 15, and 16) provide easy determination of pressure drops for specific fluids and pipe standards. In addition, tables of pressure drops can be found in Crane Co. (1976) and Hydraulic Institute (1990).

The Reynolds numbers represented on the charts in Figures 14, 15, and 16 are all in the turbulent flow regime. For smaller pipes and/or lower velocities, the Reynolds number may fall into the laminar regime, in which the Colebrook friction factors are no longer valid.

Most tables and charts for water are calculated for properties at 15°C. Using these for hot water introduces some error, although the answers are conservative (i.e., cold-water calculations overstate the pressure drop for hot water). Using 15°C water charts for 90°C water should not result in errors in Δp exceeding 20%.

Table 26 Allowable Number of 25 mm Flush Valves Served by Various Sizes of Water Pipe*

Pipe Size, mm	No. of 25 mm Flush Valves
32	1
40	2 to 4
50	5 to 12
65	13 to 25
75	26 to 40
100	41 to 100

*Two 20 mm flush valves are assumed equal to one 25 mm flush valve but can be served by a 25 mm pipe. Water pipe sizing must consider demand factor, available pressure, and length of run.

Range of Usage of Pressure Drop Charts

General Design Range. The general range of pipe friction loss used for design of hydronic systems is between 100 and 400 Pa per metre of pipe. A value of 250 Pa/m represents the mean to which most systems are designed. Wider ranges may be used in specific designs if certain precautions are taken.

Piping Noise. Closed-loop hydronic system piping is generally sized below certain arbitrary upper limits, such as a velocity limit of 1.2 m/s for 50 mm pipe and under, and a pressure drop limit of 400 Pa/m for piping over 50 mm in diameter. Velocities in excess of 1.2 m/s can be used in piping of larger size. This limitation is generally accepted, although it is based on relatively inconclusive experience with noise in piping. **Water velocity noise** is not caused by water but by free air, sharp pressure drops, turbulence, or a combination of these, that cause cavitation or flashing of water into steam. Therefore, higher velocities may be used if proper precautions are taken to eliminate air and turbulence.

Air Separation

Air in hydronic systems is usually undesirable because it causes flow noise, allows oxygen to react with piping materials, and sometimes even prevents flow in parts of a system. Air may enter a system at an air/water interface in an open system or in an expansion tank in a closed system, or it may be brought in dissolved in makeup water. Most hydronic systems use air separation devices to remove air. The solubility of air in water increases with pressure and decreases with temperature; thus, ***separation of air from water is best achieved at the point of lowest pressure and/or highest temperature in a system***. For more information, see Chapter 13 of the 2020 *ASHRAE Handbook—HVAC Systems and Equipment*.

Table 27 Equivalent Length in Metres of Pipe for 90° Elbows

Open globe valve	12.0	17.0

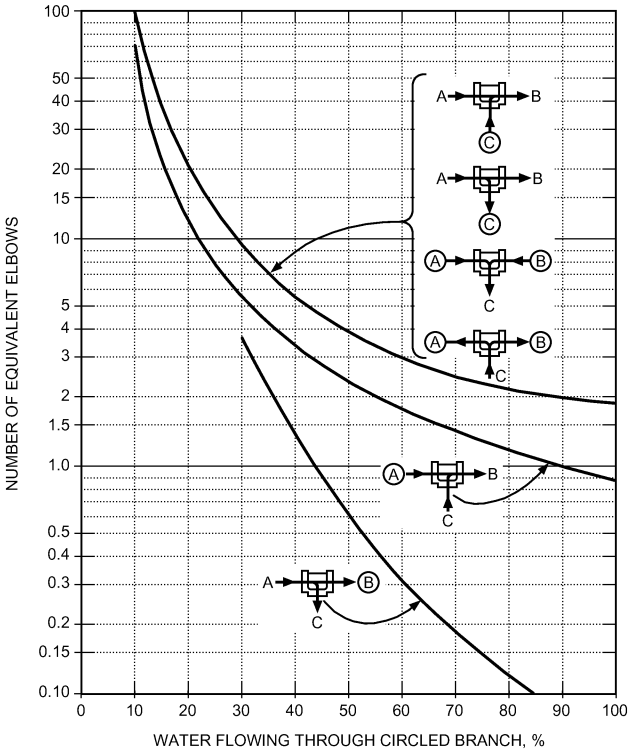
Sources: Giesecke (1926) and Giesecke and Badgett (1931, 1932a).
*See Table 10 for equivalent length of one elbow.

In the absence of venting, air can be entrained in the water and carried to separation units at flow velocities of 0.5 to 0.6 m/s or more in pipe 50 mm and under. Minimum velocities of 0.6 m/s are therefore recommended. For pipe sizes 50 mm and over, minimum velocities corresponding to a pressure loss of 75 Pa are normally used. Maintaining minimum velocities is particularly important in the upper floors of high-rise buildings where the air tends to come out of solution because of reduced pressures. Higher velocities should be used in **downcomer** return mains feeding into air separation units located in the basement.

Example 5. Determine the iron pipe size for a circuit requiring 1.25 L/s flow.

Solution: Enter Figure 4 at 1.25 L/s, read up to pipe size within normal design range (100 to 400 Pa/m), and select 40 mm. Velocity is 1 m/s and pressure loss is 300 Pa/m.

Valve and Fitting Pressure Drop



Valves and fittings can be listed in elbow equivalents, with an elbow being equivalent to a length of straight pipe. Table 27 lists equivalent lengths of 90° elbows; Table 28 lists elbow equivalents for valves and fittings for iron and copper.

Example 6. Determine equivalent length of pipe for a 100 mm open gate valve at a flow velocity of approximately 1.33 m/s.

Solution: From Table 27, at 1.33 m/s, each elbow is equivalent to 3.2 m of 100 mm pipe. From Table 28, the gate valve is equivalent to 0.5 elbows. The actual equivalent pipe length (added to measured circuit length for pressure drop determination) will be 3.2 × 0.5, or 1.6 m of 100 mm.

Tee Fitting Pressure Drop. Pressure drop through pipe tees varies with flow through the branch. Figure 17 shows pressure drops for nominal 25 mm tees of equal inlet and outlet sizes and for the flow patterns shown. Idelchik (1986) also presents data for threaded tees.

Different investigators present tee loss data in different forms,

Notes:
1. Chart is based on straight tees (i.e., branches A, B, and C are the same size).
2. Pressure loss in desired circuit is obtained by selecting proper curve according to illustrations, determining flow at circled branch, and multiplying pressure loss for same size elbow at flow rate in circled branch by equivalent elbows indicated.
3. When outlet size is reduced, equivalent elbows shown do not apply. Therefore, maximum loss for any circuit for any flow will not exceed 2 elbow equivalents at maximum flow occurring in any branch of tee.
4. Top curve is average of 4 curves, one for each circuit shown.

Fig. 17 Elbow Equivalents of Tees at Various Flow Conditions
(Giesecke and Badgett 1931, 1932b)

sources. As an estimate of the upper limit to tee losses, a pressure or head loss coefficient of 1.0 may be assumed for entering and leaving flows (i.e., $\Delta p = 1.0\rho V_{in}^2/2 + 1.0\rho V_{out}^2/2$).

Example 7. Determine the pressure or head losses for a 25 mm (all openings) threaded pipe tee flowing 25% to the side branch, 75% through. The entering flow is 1 L/s (1.79 m/s).

Solution: From Figure 17, bottom curve, the number of equivalent elbows for the through-flow is 0.15 elbows; the through-flow is 0.75 L/s (1.34 m/s); and the pressure drop is based on the exit flow rate. Table 27 gives the equivalent length of a 25 mm elbow at 1.33 m/s as 0.8 m. Using Figure 14, the head loss is 900 Pa/m for 25 mm pipe and 0.75 L/s flow.

Licensed for single user. © 2021 ASHRAE, Inc.

Δp = (0.15)(0.8)(900)
= 108 Pa = 0.108 kPa pressure drop
Δh = (0.15)(0.8)(900)/(1000)(9.8)
= 0.0110 m head loss

From Figure 17, top curve, the number of equivalent elbows for the branch flow of 25% is 13 elbows; the branch flow is 0.75 L/s (0.45 m/s); and the head loss or pressure drop is based on the exit flow rate. Table 27 gives the equivalent of a 25 mm elbow at 0.45 m/s as 0.75 m. Using Figure 14, the pressure drop is 130 Pa/m for 25 mm pipe and 0.25 L/s flow.

Δp = (13)(0.75)(130)
= 1268 Pa = 1.268 kPa pressure drop
Δh = (13)(0.75)(130)/(1000)(9.8)
= 0.129 m head loss

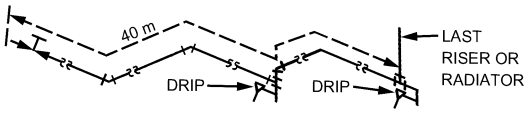
3.3 STEAM PIPING

Pressure losses in steam piping for flows of dry or nearly dry steam are governed by Equations (2) to (8) in the section on Design Equations. This section incorporates these principles with other information specific to steam systems.

Pipe Sizes

Required pipe sizes for a given load in steam heating depend on the following factors:

- The initial pressure and the total pressure drop that can be allowed between the source of supply and the end of the return system
- The maximum velocity of steam allowable for quiet and dependable operation of the system, taking into consideration the direction of condensate flow
- The equivalent length of the run from the boiler or source of steam supply to the farthest heating unit



Initial Pressure and Pressure Drop. Table 29 lists pressure drops commonly used with corresponding initial steam pressures for sizing steam piping.

Several factors, such as initial pressure and pressure required at the end of the line, should be considered, but it is most important that (1) the total pressure drop does not exceed the initial gage pressure of the system (in practice, it should never exceed one-half the initial gage pressure); (2) pressure drop is not great enough to cause excessive velocities; (3) a constant initial pressure is maintained, except on systems specially designed for varying initial pressures (e.g., subatmospheric pressure), that normally operate under controlled partial vacuums; and (4) for gravity return systems, pressure drop to heating units does not exceed the water column available for removing condensate (i.e., height above the boiler water line of the lowest point on the steam main, on the heating units, or on the dry return).

Maximum Velocity. For quiet operation, steam velocity should be 40 to 60 m/s, with a maximum of 75 m/s. The lower the velocity, the quieter the system. When condensate must flow against the steam, even in limited quantity, the steam's velocity must not exceed limits above which the disturbance between the steam and the counterflowing water may (1) produce objectionable sound, such as water hammer, or (2) result in the retention of water in certain parts of the system until the steam flow is reduced sufficiently to allow water to pass. These limits are a function of (1) pipe size; (2) pitch of the pipe if it runs horizontally; (3) quantity of condensate flowing against the steam; and (4) freedom of the piping from water pockets that, under certain conditions, act as a restriction in pipe size. Table 30 lists maximum capacities for various size steam lines.

Equivalent Length of Run. All tables for the flow of steam in pipes based on pressure drop must allow for pipe friction, as well as for the resistance of fittings and valves. These resistances are generally stated in terms of straight pipe; that is, a certain fitting produces a drop in pressure equivalent to the stated length of straight run of the same size of pipe. Table 31 gives the length of straight pipe usually allowed for the more common types of fittings and valves. In all pipe sizing tables in this chapter, *length of run* refers to the *equivalent length of run* as distinguished from the *actual length* of pipe. A common sizing method is to assume the length of run and to check this assumption after pipes are sized. For this purpose, length of run is usually assumed to be double the actual length of pipe.

Example 8. Using Table 31, determine the equivalent length of pipe for the run shown.

Measured length = 40 m
100 mm gate valve = 0.6 m
Four 100 mm elbows = 10 m
Total = 50.6 m

Table 29 Pressure Drops Used for Sizing Steam Pipe[a]

Initial Steam Pressure, kPa[b]	Pressure Drop, Pa/m	Total Pressure Drop in Steam Supply Piping, kPa
Vacuum return	30 to 60	7 to 14
101	7	0.4
108	30	0.4 to 1.7
115	30	3.5

Sizing Charts

Figure 18 is the basic chart for determining the flow rate and velocity of steam in Schedule 40 pipe for various values of pressure drop per unit length, based on saturated steam at standard pressure (101.325 kPa). Using the multiplier chart (Figure 19), Figure 18 can be used at all saturation pressures between 101 and 1500 kPa (see Example 10).

3.4 LOW-PRESSURE STEAM PIPING

Values in Table 32 (taken from Figure 18) provide a more rapid means of selecting pipe sizes for the various pressure drops listed and for systems operated at 25 and 85 kPa (gage). The flow rates shown for 25 kPa can be used for saturated pressures from 7 to 41 kPa, and those shown for 85 kPa can be used for saturated pressures from 55 to 110 kPa with an error not exceeding 8%.

Both Figure 18 and Table 32 can be used where the flow of condensate does not inhibit the flow of steam. Columns B and C of Table 33 are used in cases where steam and condensate flow in opposite directions, as in risers or runouts that are not dripped. Columns D, E, and F are for one-pipe systems and include risers, radiator valves and vertical connections, and radiator and riser runout sizes, all of which are based on the critical velocity of the steam to allow counterflow of condensate without noise.

Return piping can be sized by Table 34, using pipe capacities for wet, dry, and vacuum return lines for several values of pressure drop per metres of equivalent length.

Example 9. What pressure drop should be used for the steam piping of a system if the measured length of the longest run is 150 m, and the initial pressure must not exceed 14 kPa above atmospheric?

Solution: It is assumed, if the measured length of the longest run is 150 m, that when the allowance for fittings is added, the equivalent length of run does not exceed 300 m. Then, with the pressure drop not over one-half of the initial pressure, the drop could be 7 kPa or less. With a pressure drop of 7 kPa and a length of run of 300 m, the drop would be 23 Pa/m; if the total drop were 3.5 kPa, the drop would be 12 Pa/m. In both cases, the pipe could be sized for a desired capacity according to Figure 18.

On completion of the sizing, the drop could be checked by taking the longest line and actually calculating the equivalent length of run from the pipe sizes determined. If the calculated drop is less than that assumed, the pipe size is adequate; if it is more, an unusual number of fittings is probably involved, and either the lines must be straightened, or the next larger pipe size must be tried.

High-Pressure Steam Piping

Many heating systems for large industrial buildings use high-pressure steam [100 to 1000 kPa (gage)]. These systems usually have unit heaters or large built-up fan units with blast heating coils.

Notes:
1. Flow rate is in g/s at initial saturation pressures of 25 and 85 kPa (gage). Flow is based on Moody friction factor, where the flow of condensate does not inhibit the flow of steam.
2. The flow rates at 25 kPa cover saturated pressure from 7 to 41 kPa, and the rates at 85 kPa cover saturated pressure from 55 to 110 kPa with an error not exceeding 8%.
3. The steam velocities corresponding to the flow rates given in this table can be found from Figures 18 and 19.

Licensed for single user. © 2021 ASHRAE, Inc.

Notes: Based on Moody Friction Factor where flow of condensate does not inhibit flow of steam.
See Figure 19 for obtaining flow rates and velocities of all saturation pressures between 101 to 1500 kPa; see also Examples 9 and 10.

300	1450	1200	—	—	—
400	2770	2390	—	—	—

Notes:
1. For one- or two-pipe systems in which condensate flows against steam flow.
2. Steam at average pressure of 7 kPa (gage) used as basis of calculating capacities.

[a]Do not use column B for pressure drops of less than 13 Pa per metre of equivalent run. Use Figure 18 or Table 31 instead.
[b]Pitch of horizontal runouts to risers and radiators should be not less than 40 mm/m. Where this pitch cannot be obtained, runouts over 2.5 m in length should be one pipe size larger than that called for in this table.
[c]Do not use column D for pressure drops of less than 9 Pa per metre of equivalent run, except on sizes 80 mm and over. Use Figure 18 or Table 31 instead.

Temperatures are controlled by a modulating or throttling thermostatic valve or by face or bypass dampers controlled by the room air temperature, fan inlet, or fan outlet.

Use of Basic and Velocity Multiplier Charts

Example 10. Given a flow rate of 0.85 kg/s, an initial steam pressure of 800 kPa, and a pressure drop of 2.5 kPa/m, find the size of Schedule 40 pipe required and the velocity of steam in the pipe.

Solution: The following steps are shown by the broken line on Figures 18 and 19.

1. Enter Figure 18 at a flow rate of 0.85 kg/s, and move vertically to the horizontal line at 800 kPa
2. Follow along inclined multiplier line (upward and to the left) to horizontal 101 kPa line. The equivalent mass flow at 101 kPa is about 0.30 kg/s.
3. Follow the 0.30 kg/s line vertically until it intersects the horizontal line at 2500 Pa/m pressure drop. Nominal pipe size is 65 mm. The equivalent steam velocity at 101 kPa is about 165 m/s.
4. To find the steam velocity at 800 kPa, locate the value of 165 m/s on the ordinate of the velocity multiplier chart (Figure 19) at 101 kPa.
5. Move along the inclined multiplier line (downward and to the right) until it intersects the vertical 800 kPa pressure line. The velocity is about 65 m/s.

Note: Steps 1 through 5 would be rearranged or reversed if different data were given.

3.5 STEAM CONDENSATE SYSTEMS

The majority of steam systems used in heating applications are two-pipe systems (steam pipe and condensate pipe). This discussion is limited to sizing the condensate lines in two-pipe systems.

Two-Pipe Systems

When steam is used for heating a liquid to 102°C or less (e.g., in domestic water heat exchangers, domestic heating water converters,

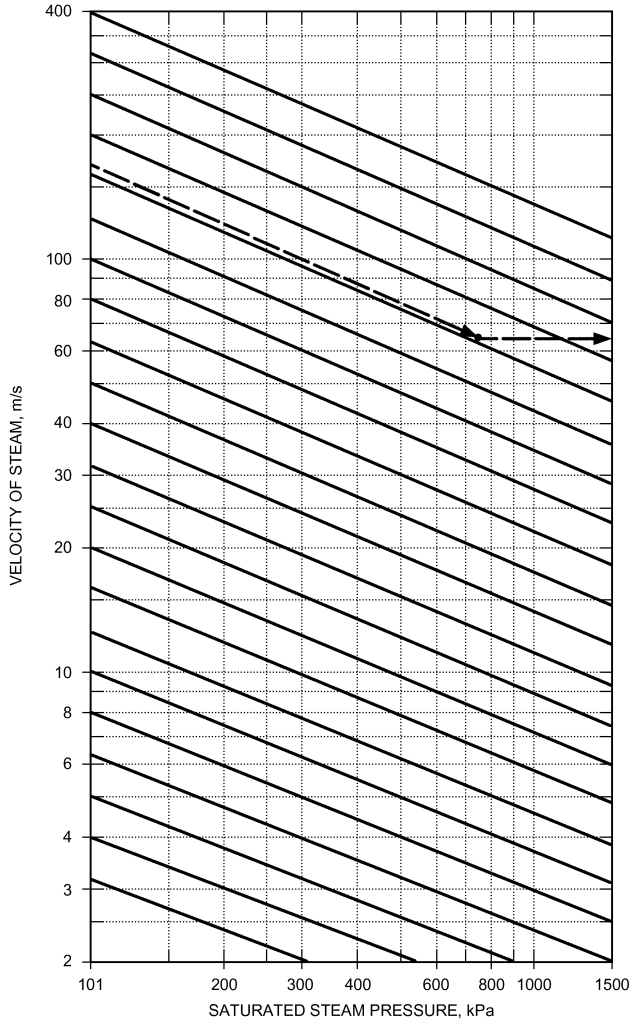

Fig. 19 Velocity Multiplier Chart for Figure 18

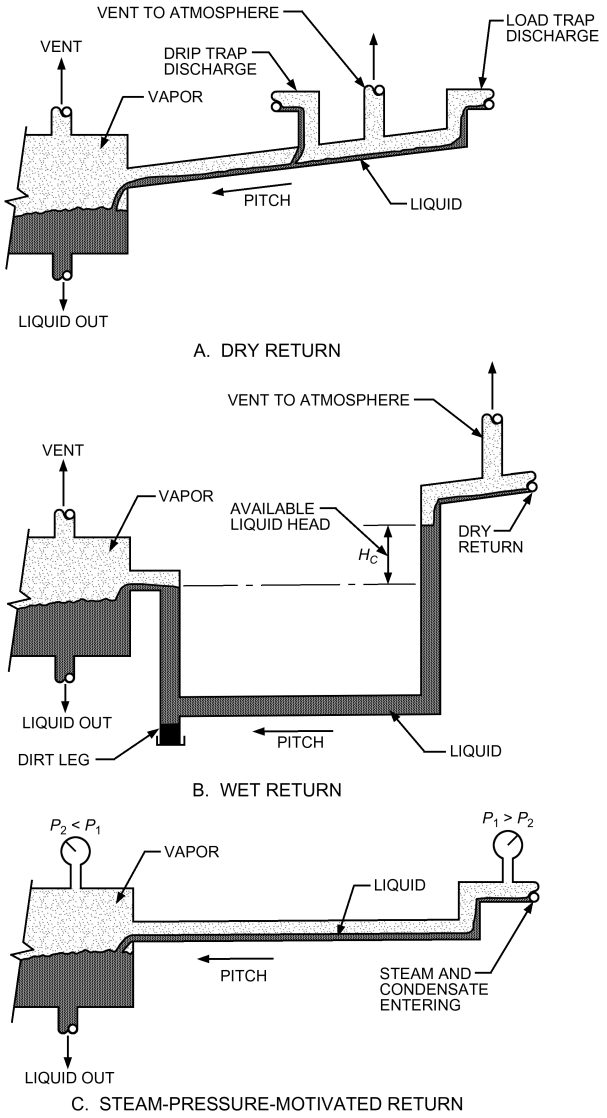

Fig. 20 Types of Condensate Return Systems

or air-heating coils), the devices are usually provided with a steam control valve. As the control valve throttles, the absolute pressure in the load device decreases, removing all pressure motivation for flow in the condensate return system. To ensure the flow of steam condensate from the load device through the trap and into the return system, it is necessary to provide a vacuum breaker on the device ahead of the trap. This ensures a minimum pressure at the trap inlet of atmospheric pressure plus whatever liquid leg the designer has provided. Then, to ensure flow through the trap, it is necessary to design the condensate system so that it will never have a pressure above atmospheric in the condensate return line.

Vented (Open) Return Systems. To achieve this pressure requirement, the condensate return line is usually vented to the atmosphere (1) near the point of entrance of the flow streams from the load traps, (2) in proximity to all connections from drip traps, and (3) at transfer pumps or feedwater receivers.

The dry return lines in a vented return system have flowing liquid in the bottom of the line and gas or vapor in the top (Figure 20A). The liquid is the condensate, and the gas may be steam, air, or a mixture of the two. The flow phenomenon for these dry return systems is open channel flow, which is best described by the **Manning equation**:

$$Q = \frac{1.00 A r^{2/3} S^{1/2}}{n} \quad (22)$$

where

Q = volumetric flow rate, m^3/s
A = cross-sectional area of conduit, m^2
r = hydraulic radius of conduit, m
n = coefficient of roughness (usually 0.012)
S = slope of conduit, m/m

Table 35 is a solution to Equation (22) that shows pipe size capacities for steel pipes with various pitches. Recommended practice is to size vertical lines by the maximum pitch shown, although they would actually have a capacity far in excess of that shown. As pitch increases, hydraulic jump that could fill the pipe and other transient effects that could cause water hammer should be avoided. Flow values in Table 35 are calculated for Schedule 40 steel pipe, with a factor of safety of 3.0, and can be used for copper pipes of the same nominal pipe size.

The flow characteristics of **wet return lines** (Figure 20B) are best described by the Darcy-Weisbach equation [Equation (1)]. The motivation for flow is the fluid pressure difference between the entering section of the flooded line and the leaving section. It is common practice, in addition to providing for the fluid pressure

Licensed for single user. © 2021 ASHRAE, Inc.

differential, to slope the return in the direction of flow to a collection point such as a dirt leg to clear the line of sediment or solids. Table 36 is a solution to Equation (1) that shows pipe size capacity for steel pipes with various available fluid pressures. Table 36 can also be used for copper tubing of equal nominal pipe size.

Nonvented (Closed) Return Systems. For systems with a continual steam pressure difference between the point where the condensate enters the line and the point where it leaves (Figure 20C), Table 34 or Table 35, as applicable, can be used for sizing the condensate lines. Although these tables express condensate capacity without slope, common practice is to slope the lines in the direction of flow to a collection point (similar to wet returns) to clear the lines of sediment or solids.

When saturated condensate at pressures above the return system pressure enters the return (condensate) mains, some of the liquid flashes to steam. This occurs typically at drip traps into a vented return system or at load traps leaving process load devices that are not valve controlled and typically have no subcooling. If the return main is vented, the vent lines relieve any excessive pressure and prevent a backpressure phenomenon that could restrict flow through traps from valved loads; the pipe sizing would be as described for vented dry returns. If the return line is not vented, flash steam causes a pressure rise at that point and the piping could be sized as described for closed returns, and in accordance with Table 34 or Table 37, as applicable.

Passage of fluid through the steam trap is a throttling or constant-enthalpy process. The resulting fluid on the downstream side of the trap can be a mixture of saturated liquid and vapor. Thus, in nonvented returns, it is important to understand the fluid's condition when it enters the return line from the trap.

The condition of the condensate downstream of the trap can be expressed by the quality x, defined as

$$x = \frac{m_v}{m_l + m_v} \tag{23}$$

where

m_v = mass of saturated vapor in condensate
m_l = mass of saturated liquid in condensate

Likewise, the volume fraction V_c of the vapor in the condensate is expressed as

$$V_c = \frac{V_v}{V_l + V_v} \tag{24}$$

where

V_v = volume of saturated vapor in condensate
V_l = volume of saturated liquid in condensate

The quality and the volume fraction of the condensate downstream of the trap can also be estimated from Equations (25) and (26), respectively.

$$x = \frac{h_1 - h_{f_2}}{h_{g_2} - h_{f_2}} \tag{25}$$

$$V_c = \frac{x v_{g_2}}{v_{f_2}(1-x) + x v_{g_2}} \tag{26}$$

where

h_1 = enthalpy of liquid condensate entering trap evaluated at supply pressure for saturated condensate or at saturation pressure corresponding to temperature of subcooled liquid condensate
h_{f_2} = enthalpy of saturated liquid at return or downstream pressure of trap
h_{g_2} = enthalpy of saturated vapor at return or downstream pressure of trap
v_{f_2} = specific volume of saturated liquid at return or downstream pressure of trap
v_{g_2} = specific volume of saturated vapor at return or downstream pressure of trap.

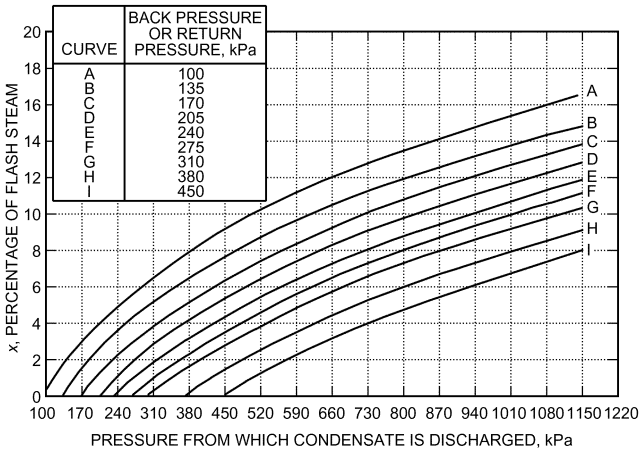

Fig. 21 Working Chart for Determining Percentage of Flash Steam (Quality)

Table 38 presents some values for quality and volume fraction for typical supply and return pressures in heating and ventilating systems. Note that the percent of vapor on a mass basis x is small, although the percent of vapor on a volume basis V_c is very large. This indicates that the return pipe cross section is predominantly occupied by vapor. Figure 21 is a working chart to determine the quality of condensate entering the return line from the trap for various combinations of supply and return pressures. If the liquid is subcooled entering the trap, the saturation pressure corresponding to the liquid temperature should be used for the supply or upstream pressure. Typical pressures in the return line are given in Table 39.

One-Pipe Systems

Gravity one-pipe air vent systems in which steam and condensate flow in the same pipe, frequently in opposite directions, are considered obsolete and are no longer being installed. Chapter 33 of the 1993 *ASHRAE Handbook—Fundamentals* or earlier ASHRAE Handbook volumes include descriptions of and design information for one-pipe systems.

3.6 GAS PIPING

Piping for gas appliances should be of adequate size and installed so that it provides a supply of gas sufficient to meet the maximum demand without undue loss of pressure between the point of supply (the meter) and the appliance. The size of gas pipe required depends on (1) maximum gas consumption to be provided, (2) length of pipe and number of fittings, (3) allowable pressure loss from the outlet of the meter to the appliance, and (4) density of the gas.

Insufficient gas flow from excessive pressure losses in gas supply lines can cause inefficient operation of gas-fired appliances and sometimes create hazardous operations. Gas-fired appliances are normally equipped with a data plate giving information on maximum gas flow requirements or input as well as inlet gas pressure requirements. The local gas utility can give the gas pressure available at the utility's gas meter. Using this information, the required size of gas piping can be calculated for satisfactory operation of the appliance(s).

Table 40 gives pipe capacities for gas flow for up to 60 m of pipe based on a gas density of 0.735 kg/m^3. Capacities for pressures less than 10 kPa may also be determined by the following equation from NFPA/IAS *National Fuel Gas Code* (NFPA *Standard* 54/ANSI *Standard* Z223.1):

$$Q = 0.0001 d^{2.623} (\Delta p / CL)^{0.541} \quad (27)$$

where

Q = flow rate at 15°C and 101 kPa, L/s

Table 40 Maximum Capacity of Gas Pipe in Litres per Second

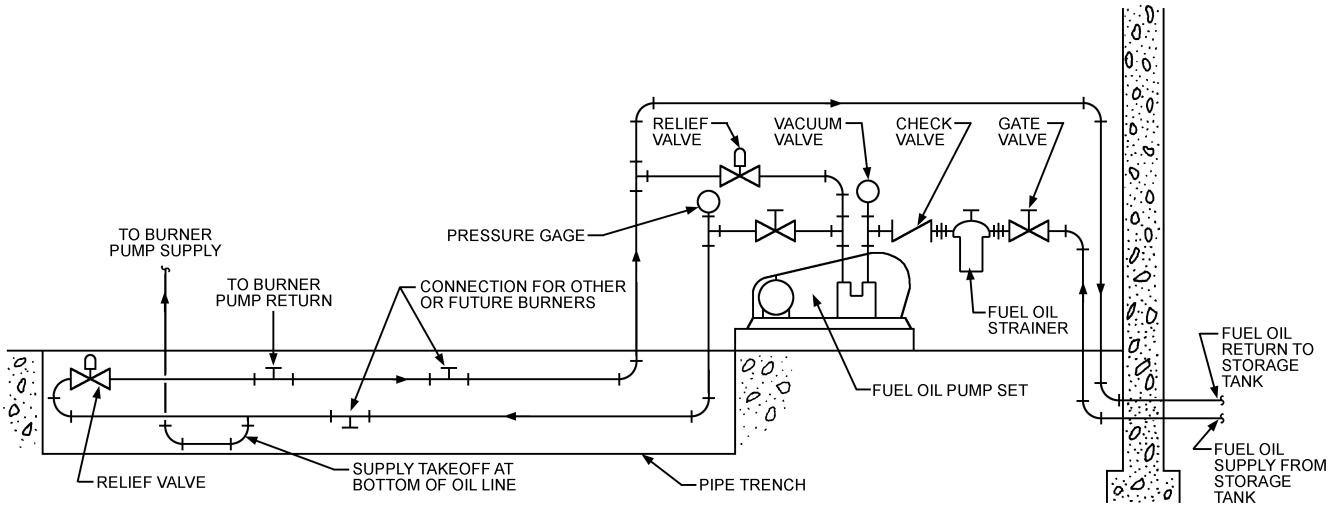

Fig. 22 Typical Oil Circulating Loop

d = inside diameter of pipe, mm
Δp = pressure drop, Pa
C = factor for viscosity, density, and temperature
= $0.00223(t + 273)s^{0.848}\mu^{0.152}$
t = temperature, °C
s = ratio of density of gas to density of air at 15°C and 101 kPa
μ = viscosity of gas, μPa·s (12 for natural gas, 8 for propane)
L = pipe length, m

Gas service in buildings is generally delivered in the low-pressure range of 1.7 kPa (gage). The maximum pressure drop allowable in piping systems at this pressure is generally 125 Pa but is subject to regulation by local building, plumbing, and gas appliance codes [see also the NFPA/IAS *National Fuel Gas Code* (NFPA *Standard* 54/ANSI *Standard* Z223.1)].

Where large quantities of gas are required or where long lengths of pipe are used (e.g., in industrial buildings), low-pressure limitations result in large pipe sizes. Local codes may allow (and local gas companies may deliver) gas at higher pressures [e.g., 15, 35, or 70 kPa (gage)]. Under these conditions, an allowable pressure drop of 10% of the initial pressure is used, and pipe sizes can be reduced significantly. Gas pressure regulators at the appliance must be specified to accommodate higher inlet pressures. NFPA/IAS (2012) provides information on pipe sizing for various inlet pressures and pressure drops at higher pressures. More complete information on gas piping can be found in the *Gas Engineers' Handbook* (1970).

3.7 FUEL OIL PIPING

The pipe used to convey fuel oil to oil-fired appliances must be large enough to maintain low pump suction pressure and, in the case of circulating loop systems, to prevent overpressure at the burner oil pump inlet. Pipe materials must be compatible with the fuel and must be carefully assembled to eliminate all leaks. Leaks in suction lines can cause pumping problems that result in unreliable burner operation. Leaks in pressurized lines create fire hazards. Cast-iron or aluminum fittings and pipe are unacceptable. Pipe joint compounds must be selected carefully.

Oil pump suction lines should be sized so that at maximum suction line flow conditions, the maximum vacuum will not exceed 34 kPa for distillate grade fuels and 50 kPa for residual oils. Oil supply lines to burner oil pumps should not be pressurized by circulating loop systems or aboveground oil storage tanks to more than 34 kPa, or pump shaft seals may fail. A typical oil circulating loop system is shown in Figure 22.

Table 41 Recommended Nominal Size for Fuel Oil Suction Lines from Tank to Pump (Residual Grades No. 5 and No. 6)

Pumping Rate, L/h	Length of Run in Metres at Maximum Suction Lift of 4.5 kPa									
	10	20	30	40	50	60	70	80	90	100
50	40	40	40	50	50	50	65	65	65	80
100	40	40	50	50	65	65	65	65	80	80
200	40	50	50	50	65	65	65	80	80	80
300	50	50	65	65	65	80	80	80	80	80
400	50	50	65	65	80	80	80	80	80	100
500	50	65	65	65	80	80	80	80	100	100
600	65	65	65	80	80	80	100	100	100	100
700	65	65	65	80	80	100	100	100	100	100
800	65	65	80	80	100	100	100	100	100	100

Notes:
1. Sizes (in millimetres) are nominal.
2. Pipe sizes smaller than 25 mm ISO are not recommended for use with residual grade fuel oils.
3. Lines conveying fuel oil from pump discharge port to burners and tank return may be reduced by one or two sizes, depending on piping length and pressure losses.

In assembling long fuel pipe lines, be careful to avoid air pockets. On overhead circulating loops, the line should vent air at all high points. Oil supply loops for one or more burners should be the continuous circulation type, with excess fuel returned to the storage tank. Dead-ended pressurized loops can be used, but air or vapor venting is more problematic.

Where valves are used, select ball or gate valves. Globe valves are not recommended because of their high pressure drop characteristics.

Oil lines should be tested after installation, particularly if they are buried, enclosed, or otherwise inaccessible. Failure to perform this test is a frequent cause of later operating difficulties. A suction line can be hydrostatically tested at 1.5 times its maximum operating pressure or at a vacuum of not less than 70 kPa. Pressure or vacuum tests should continue for at least 60 min. If there is no noticeable drop in the initial test pressure, the lines can be considered tight.

Pipe Sizes for Heavy Oil

Tables 41 and 42 give recommended pipe sizes for handling No. 5 and No. 6 oils (residual grades) and No. 1 and No. 2 oils (distillate

Note: Sizes (in millimetres) are nominal.

grades), respectively. Storage tanks and piping and pumping facilities for delivering the oil from the tank to the burner are important considerations in the design of an industrial oil-burning system. The construction and location of the tank and oil piping are usually subject to local regulations and National Fire Protection Association (NFPA) *Standards* 30 and 31.
